Preface

The AIEE *Transactions* for 1956 (volume 75) is published in three parts: Part I. Communication and Electronics; Part II. Applications and Industry; and Part III. Power Apparatus and Systems. The papers in each of the three parts are classified according to subject matter as follows:

Part I. Communication and Electronics

- Communication Switching Systems
- Communication Theory
- Radio Communications Systems
- Special Communications Applications
- Telegraph Systems
- Television and Aural Broadcasting Systems
- Wire Communications Systems
- Basic Sciences
- Computing Devices
- Dielectrics
- Electrical Techniques in Medicine and Biology
- Electronics
- Instruments and Measurements
- Magnetic Amplifiers
- Metallic Rectifiers
- Nucleonics
- Solid State Devices

Part II. Applications and Industry

- Air Transportation
- Domestic and Commercial Applications
- Land Transportation
- Marine Transportation
- Production and Application of Light
- Chemical Industry
- Electric Heating
- Electric Welding
- Feedback Control Systems
- General Industry Applications
- Industrial Control
- Industrial Power Rectifiers
- Industrial Power Systems
- Mining and Metal Industry
- Petroleum Industry

Part III. Power Apparatus and Systems

- Carrier Current
- Insulated Conductors
- Power Generation
- Protective Devices
- Relays
- Rotating Machinery
- Substations
- Switchgear
- System Engineering
- Transformers
- Transmission and Distribution

- Education
- Safety
- Research

Each part has been indexed separately in the back of that particular part. The three parts are not cross-referenced; hence the user should determine first whether the subject matter of the paper desired is in the field of communication and electronics, applications and industry, or power apparatus and systems. Papers are listed in the subject index under several key words in the titles. The original numbers assigned to the papers are given in the author index. Volume 75 contains the technical papers and related discussions presented at these meetings:

1. Winter General Meeting, New York, N. Y., January 30–February 3, 1956.
2. South West District Meeting, Dallas, Tex., April 2–4, 1956.
3. Great Lakes District Meeting, Fort Wayne, Ind., April 16–18, 1956.
4. North Eastern District Meeting, Rochester, N. Y., May 2–4, 1956.
5. Summer and Pacific General Meeting, San Francisco, Calif., June 25–29, 1956.
6. Fall General Meeting, Chicago, Ill., October 1–5, 1956.

Statements and opinions given in the papers and discussions published in *Transactions* are the expressions of the contributors for which the American Institute of Electrical Engineers assumes no responsibility.

Communication and Electronics Index for 1956

1. Technical Subject Index

A2A Video System, Field Experience with the. Gast. 710–16
A-C Bridge to Measure Core Loss at High Inductions, The Use of an. Cooter, Harris....252–5; disc. 256
A-C Kelvin Bridge for the Audio-Frequency Range, An. Dunfee....123–7; disc. 127
Accuracy Obtainable with Multiplier Phototubes, Synchronization. Levi....603–06
Accurate Determination of the Capacitance of a Thin Rectangular Plate. Reitan, Higgins....761–6; disc. 766
Air-Dielectric Cable, Styroflex Aluminum-Sheathed. Merrell, McKean, Arbuthnott...669–74; disc. 674
Air Purification, Heat as a Means of. Beckett, Clifton. 373–7
Alternating Current Control of the Half-Wave Bridge Magnetic Amplifier. Bernstein, Schmitz....433–8
Aluminum-Sheathed Air-Dielectric Cable, Styroflex. Merrell, McKean, Arbuthnott...669–74; disc. 674
Amplifiers, Application of Junction Transistors to Carrier-Frequency Computing. Curtin....746–52; disc. 752
Amplifiers for Flight Simulators, Transistor Analogue Computing. Weyrick....338–42
Amplifiers, Hysteresis Loops in Dielectric. Wingrove, Depian, Shevel....283–8; disc. 288
Amplifiers, Optimum Design of Common Emitter Transistor Audio. Vallese....391–5
Amplifiers, Temperature Stabilization of Transistor. Vallese....379–84
Amplifiers with Switched Mode of Operation, Transistor Power. Milnes....368–72
Amplifiers with 2-Phase Motor Load, Measurements on High-Speed Magnetic Servo. Geyger.......242–8
Analogue Computation with Magnetic Cores, Transcendental Function. Schaefer, Van Allen....160–4; disc. 164
Analogue Computer Generation of Probability Distributions for Operations Research. Diamantides.. 86–91
Analogue Computer, Linear Programming on an Electronic. Pyne....139–42; disc. 142
Analogue Computer Synthesis and Error Matrices. Honnell, Horn....26–32
Analogue Computing Amplifiers for Flight Simulators, Transistor. Weyrick....338–42
Analogue to Digital Converters, Cyclic Decimal Codes for. O'Brien....120–2
Analysis, A Phasor Method of Nonlinear Network. Neal....630–6; disc. 636
Analysis and Design of the Ferroelectric Resonant Trigger Pair, An. Gremer....404–07
Analysis and Design, The Ferroresonant Trigger Pair:. Spitzer....407–16
Analysis of Instability and Response of Reactors with Rectangular Hysteresis Loop Core Material in Series with Capacitors. Salihi..296–305; disc. 305
Analysis of Junction Transistor Flip-Flops, D-C Graphical. Bashkow....1–7
Analysis of Linear Sampled-Data Systems with Finite Pulse Width: Open Loop. Farmanfarma..808–19
Analysis of Sampled Data Servomechanisms Performed on the IBM Type 650, The. Tostanoski....446–50
Analysis with a Digital Computation System, Automatic Network. Wong, Kochen........172–5; disc. 176
Analytical Design and Evaluation of Electromagnets, The. Kelly, Wallace....675–80
Antennas, Impedance of Thin-Wire Loop. Storer.... 606–18
Application of a Digital Computer to the Design of Power Transformers to Specification. Moore, Duboc, Zaphyr....134–7; disc. 137
Application of Junction Transistors to Carrier-Frequency Computing Amplifiers. Curtin...746–52; disc. 752
Application of Statistical Techniques to Electron Tubes for Use in a 4,000 Mile Transmission System. Van Haste....50–4
Application of the Type-P1 Carrier System to Rural Telephone Lines. Howard......205–13; disc. 214
Approximation Problem, Note on the. Balabanian.72–5
Arc in a Magnetic Field, Properties of a D-C. Winsor, Lee....143–8; disc. 148
Arc-Resistant Molding Materials and Finishes. Sterling 776–80
Atlantic Link, Power-Feed Equipment for the North. Meszaros, Spencer....890–8
Atlantic Link, Repeater Design for the North. Gleichmann, Lince, Wooley, Braga....865–77
Atlantic Link, Repeater Production for the North. Lamb, Heffner....877–89
Atlantic Link, System Design for the North. Lewis, Tucker, Lovell, Fraser....850–64
Atomic-Wave Functions, A Digital Computer Program for Determining. Piper....152–5
Audio Amplifiers, Optimum Design of Common-Emitter Transistor. Vallese....391–5
Audio-Frequency Range, An A-C Kelvin Bridge for the. Dunfee....123–7; disc. 127
Automatic Dispatch System for Half-Duplex Teletypewriter Lines. Maxwell, Farrar....441–5
Automatic Manufacturing Facilities for Reed Switches, The Development of. Hosford....496–500
Automatic Network Analysis with a Digital Computation System. Wong, Kochen....172–5; disc. 176
Automatic Protection Switching for TD-2 Radio System. Klemm....520–7
Axis into Two Parallel R-C Ladders and an Ideal Transformer, Synthesis of Transfer Functions with Poles Restricted to the Negative Real. Malti, Sun..... ....165–71; disc. 171

B

Barium Titanate Ceramics, Investigations Concerning Polarization in. Marks, Waidelich, Monson.... 469–77
(Basic Sciences) A New Method for Treating Nonlinear Problems with Applications to Iron-Cored Oscillatory Circuits. Gohar:
  Part I. Subharmonics Do Not Exist.........771–6
(Basic Sciences) A Phasor Method of Nonlinear Network Analysis. Neal....630–6; disc. 636
(Basic Sciences) Accurate Determination of the Capacitance of a Thin Rectangular Plate. Reitan, Higgins....761–6; disc. 766
(Basic Sciences) An Analysis and Design of the Ferroelectric Resonant Trigger Pair. Gremer....404–07
(Basic Sciences) Analogue Computer Synthesis and Error Matrices. Honnell, Horn....26–32
(Basic Sciences) Analysis of Linear Sampled-Data Systems with Finite Pulse Width: Open Loop. Farmanfarma....808–19
(Basic Sciences) Computation of the Impedances of Nonuniform Lines by a Direct Method. Pipes 551–4
(Basic Sciences) Dynamax, a New Crystal and Domain-Oriented Magnetic Core Material. Howe....... ....548–50; disc. 551
(Basic Sciences) Electrical Formulas in Inch Units of Length. Williamson....61–4
(Basic Sciences) Electrical Units and Dimensions. Young....767–8; disc. 768
(Basic Sciences) Graphical Determination of the Fourier Series Coefficients. Middendorf....478–82
(Basic Sciences) Integrated s-Plane Synthesis Using 2-Way Root Locus. Zaborszky....797–801
(Basic Sciences) Investigations Concerning Polarization in Barium Titanate Ceramics. Marks, Waidelich, Monson....469–77
(Basic Sciences) Magnetic Effects of Compressional Stress at Low Field Intensities. Fischell........ ....148–51; disc. 151
(Basic Sciences) Note on the Approximation Problem. Balabanian....72–5
(Basic Sciences) Properties of a D-C Arc in a Magnetic Field. Winsor, Lee....143–8; disc. 148
(Basic Sciences) Representation of Nonlinear Characteristics by Linear Elements. Abou-Hussein..84–6
(Basic Sciences) Some Mathematical Properties of Root Loci for Control System Design. Reza.....103–08
(Basic Sciences) Subharmonic Response of the Ferroresonant Circuit with Coil Hysteresis. Brenner... 450–6
(Basic Sciences) Superposed Magnetic Fields in Materials with Rectangular Hysteresis Loops. Wakeman, Beck....562–9
(Basic Sciences) Synthesis of Transfer Functions with Poles Restricted to the Negative Real Axis into Two Parallel R-C Ladders and an Ideal Transformer. Malti, Sun....165–71; disc. 171
(Basic Sciences) The Analytical Design and Evaluation of Electromagnets. Kelly, Wallace........675–80
(Basic Sciences) The Ferroresonant Trigger Pair: Analysis and Design. Spitzer....407–16
(Basic Sciences) The Impedance Tensor of the General Machine. Yu....181–7
Behavior of a 3-Phase Magnetic Amplifier, Dynamic. Ellert....554–60; disc. 560
Bell System Teletypewriters, Static Elimination on. Bavley, Perry, Swesey....92–4
Bell System Wire Spring Relays, Design Features of. Knapp....482–6
Bilateral Switching Element, The Symmetrical Transistor as a. Trousdale....400–03
Black and White to Color Television, Conversion of Studio Lighting from. Wygant....75–8
Bonneville Power Administration, Southwest Oregon Radio System for the. Marihart, Wylie....531–8
Bridge Magnetic Amplifier, Alternating Current Control of the Half-Wave. Bernstein, Schmitz......433–8
Bridge Magnetic Amplifiers with Inductive Loads, Full-Wave. Woodson....7–9
Bridge to Measure Core Loss at High Inductions, The Use of an A-C. Cooter, Harris....252–5; disc. 256
Built-In Reliability, Microwave Facilities with. Kuck 438–41
Business Machine Data Over Standard Telegraph Channels, Transmission of. Bramhall.416–20; disc. 420

C

Cable Design and Manufacture for the Transatlantic Submarine Cable System. Lebert, Fischer, Biskeborn....907–17
Cable Laying for the Transatlantic Cable System, Route Selection and. Jack, Leech, Lewis...944–55
Cable, Lightning Protection on the Stevens Point–Wisconsin Rapids Intercity Telephone. Dowling.. 697–701
(Cable) Power-Feed Equipment for the North Atlantic Link. Meszaros, Spencer....890–8
Cable) Power-Feed System for the Newfoundland–Nova Scotia Link. Thomas, Kelly........938–43
(Cable) Repeater Design for the Newfoundland–Nova Scotia Link. Brockbank, Walker, Welsby..927–38
(Cable) Repeater Design for the North Atlantic Link. Gleichmann, Lince, Wooley, Braga.........865–77
(Cable) Repeater Production for the North Atlantic Link. Lamb, Heffner....877–89
Cable, Styroflex Aluminum-Sheathed Air-Dielectric. Merrell, McKean, Arbuthnott....669–74; disc. 674
(Cable) System Design for the Newfoundland–Nova Scotia Link. Halsey, Bampton....917–27
(Cable) System Design for the North Atlantic Link. Lewis, Tucker, Lovell, Fraser....850–64
Cable System, Electron Tubes for the Transatlantic. McNally, Metson, Veazie, Holmes........898–907
Cable System—Planning and Overall Performance, Transatlantic Telephone. Mottram, Halsey, Emling, Griffith....842–50
(Cable) Transatlantic Communications: A Historical Résumé. Kelly, Radley....841–2
Calculations with Digital Computers, Transformer Reactance. Rabins....261–7; disc. 267
Calculator, A New Five-Digit Plugboard System for Card-Programmed. Williams, Noonan.....67–71
Canada, Development of Transcontinental Communications in. Noyes, Gaudet, Bonneville.....342–52
Capability of Sealed Contact Relays. Hovgaard..466–8
Capacitance of a Thin Rectangular Plate, Accurate Determination of the. Reitan, Higgins....761–6; disc. 766
Capacitors, Analysis of Instability and Response of Reactors with Rectangular Hysteresis Loop Core Material in Series with. Salihi..296–305; disc. 305
Capacitors, Signals from Switched Ferroelectric Memory. Pulvari, McDuffie....681–5
Card-Programmed Calculator, A New Five-Digit Plugboard System for. Williams, Noonan.......67–71
Carrier-Frequency Computing Amplifiers, Application of Junction Transistors to. Curtin....746–52; disc. 752
Carrier Frequency Networks, Telephone. Wallenstein 691–7
Carrier System, Circuit and Equipment Descriptions of Type-P1. Eberhart, Hallenbeck, Perkins..195–204
Carrier System Employing Transistors, A New 4-Channel Open-Wire. Caruthers, Chaskin, Krengel..314–22
Carrier System, Objectives and General Description of the Type-P1. Boyd....188–91
Carrier System, Power Supplies for the Type-P1. Smith ....191–4; disc. 194
Carrier System to Rural Telephone Lines, Application of the Type-P1. Howard.......205–13; disc. 214

Cathode-Ray Tube, Method of Measuring Spot Size of. Kuhn, Levine....357–9; disc. 359

Series Magnetic Amplifier, The. Barker:
  Parts I and II.................819–30; disc. 830
Servo Amplifiers with 2-Phase Motor Load, Measurements on High-Speed Magnetic. Geyger..242–8
Servo Preamplifiers, A Comparison of Three Common Emitter Transistor. DeSautels...........17–25
Servomechanisms Performed on the IBM Type 650, The Analysis of Sampled Data. Tostanoski....446–50
72-Channel Radio System for Toll Telephone Service, A. Harp, Kebby..............113–19; disc. 119
704 EDPM, Numerical Integration of Differential Equations on the. Anderson, Johnson.....569–74
Several-Valued Combinational Switching Circuits. Lee, Chen...............................278–83
Shunting in Magnetic Amplifiers, Diode-. Lowrance, Dolan.....................................619–24
Signal-Discriminating Magnetic Amplifier, A. Lynn, Ringelman................................97–102
Signaling Circuit Performance, Influence of Noise on Telephone. Weber..........................636–42
Signals from Switched Ferroelectric Memory Capacitors. Pulvari, McDuffie........................681–5
Silicon Rectifier, The Fused. Henkels.........733–46
Silicon Rectifiers, Rating and Application of Germanium. Gutzwiller.........................753–7
Simplified Printing Telegraph Switching and Integrated Data Processing. Booth, Klich...........11–14
Simulators, Transistor Analogue Computing Amplifiers for Flight. Weyrick.........................338–42
Single-Transistor Magnetic-Coupled Oscillator, A. Chen, Schiewe.......................396–9; disc. 400
Size of Cathode-Ray Tube, Method of Measuring Spot. Kuhn, Levine...................357–9; disc. 359
(Solid State Devices) Temperature Stabilization of Transistor Amplifiers. Vallese...........379–84
(Solid State Devices) The Symmetrical Transistor as a Bilateral Switching Element. Troudale..400–03
Some Mathematical Properties of Root Loci for Control System Design. Reza.....................103–08
Some of the Engineering Aspects of the Machine Translation of Lauguage. Wall........580–4; disc. 585
Southwest Oregon Radio System for the Bonneville Power Administration. Marihart, Wylie...531–8
Spot Size of Cathode-Ray Tube, Method of Measuring. Kuhn, Levine..................357–9; disc. 359
Spring Relays, Design Features of Bell System Wire. Knapp.....................................482–6
Spring Relays for Communication Switching Systems, Manufacture of Wire. Rice.............513–18
Stabilization of Transistor Amplifiers, Temperature. Vallese....................................379–84
Standing-Wave Ratio of Inaccessible Load. Polk..9–11
Static Elimination on Bell System Teletypewriters. Bavley, Perry, Swezey......................92–4
Statistical Evaluation of Electrical Components, The Use of Computing Machines in the. Andrus.501–05
Statistical Techniques to Electron Tubes for Use in a 4,000 Mile Transmission System, Application of. Van Haste....................................50–4
Stature of the Crossbar Tandem Switching System, The Full. Mesar............................486–96
Stevens Point—Wisconsin Rapids Intercity Telephone Cable, Lightning Protection on. Dowling..697–701
Stretch Coupling Circuit, The Pulse. Patton...377–9
Studio Lighting from Black and White to Color Television, Conversion of. Wygant...........75–8
Styroflex Aluminum-Sheathed Air-Dielectric Cable. Merrell, McKean, Arbuthnott...669–74; disc. 674
Subharmonic Response of the Ferroresonant Circuit with Coil Hysteresis. Brenner.............450–6
Submarine Cable System, Cable Design and Manufacture for the Transatlantic. Lebert, Fischer, Blakeborn...................................907–17
Superposed Magnetic Fields in Materials with Rectangular Hysteresis Loops. Wakeman, Beck.562–9
Survey of Transformer Oil Quality, A Field. Degnan, Shimanski.....................575–9; disc. 579
Switched Ferroelectric Memory Capacitors, Signals from. Pulvari, McDuffie..................681–5
Switches, The Development of Automatic Manufacturing Facilities for Reed. Hosford......496–500
Switching and Integrated Data Processing, Simplified Printing Telegraph. Booth, Klich..........11–14
Switching Circuit, Power Transistor. Huang, Slobodzinski...................................290–6
Switching Circuits, Several Valued Combinational. Lee, Chen...................................278–83
Switching Element, The Symmetrical Transistor as a Bilateral. Troudale...................400–03
Switching for TD-2 Radio System, Automatic Protection. Klemm.............................520–7
Switching Matrix, A Magnetic Amplifier. Katz..36–41
Switching of Long-Distance Telephone Circuits, Recent Developments in 4-Wire. Molnar....... ....722–32; disc. 732
Switching System, Recent New Features for the No. 5 Crossbar. Dehn, Hersey.................457–66
Switching System, The Full Stature of the Crossbar Tandem. Mesar.........................486–96
Switching Systems, Electronics in Telephone. Joel..... ....701–09; disc. 710
Switching Transistors, Magnetic Amplifier Control of. Collins..................................585–9
Symmetrical Transistor as a Bilateral Switching Element, The. Troudale.........................400–03
Sync Pulses, A Video Visual Measuring Set with. Sproul....................................427–32
Synchronization Accuracy Obtainable with Multiplier Phototubes. Levi..........................603–06
Synchronized Computer—A University Research Project, The Wisconsin Integrally. Asmuth, Davidson, Miller, Noble, Scidmore.........330–8
Synthesis and Error Matrices, Analogue Computer. Honnell, Horn................................26–32
Synthesis of Transfer Functions with Poles Restricted to the Negative Real Axis into Two Parallel R-C Ladders and an Ideal Transformer. Malti, Sun.. ....165–71; disc. 171
Synthesis Using 2-Way Root Locus, Integrated s-Plane. Zaborszky...............................797–801
Synthesized Equivalent Network, Design of Wide-Band R-F Transformers Utilizing a. Kajihara...802–05
System Design for the Newfoundland–Nova Scotia Link. Halsey, Bampton..........................917–27
System Design for the North Atlantic Link. Lewis, Tucker, Lovell, Fraser.......................850–64
System for Half-Duplex Teletypewriter Lines, Automatic Dispatch. Maxwell, Farrar.............441–5

T

Tandem Switching System, The Full Stature of the Crossbar. Mesar............................486–96
TD-2 Radio System, Automatic Protection Switching for. Klemm..................................520–7

Technical Feasibility of Translating Languages by Machine, The. Yngve....................792–7
Technique for the Measurement of Corona Field Strength and Current Density in Electrical Precipitation, A New. Cooperman..................64–7
(Telegraph) Automatic Dispatch System for Half-Duplex Teletypewriter Lines. Maxwell, Farrar.. 441–5
Telegraph Channels, Transmission of Business Machine Data Over Standard. Bramhall..416–20; disc. 420
(Telegraph) Delay Distortion Correction. Cannon... 55–61
Telegraph Set, A Transistorized Time-Division Multiplex. Biggam..............................780–5
(Telegraph) Static Elimination on Bell System Teletypewriters. Bavley, Perry, Swezey..........92–4
Telegraph Switching and Integrated Data Processing, Simplified Printing. Booth, Klich..........11–14
(Telegraph Systems) A Data Transmission Machine. Doty, Tate.................................600–03
(Telegraph Systems) Control System for Integrated Data Processing. Easterlin..................421–7
Telegraph Transmitter, A Flat-Bed Facsimile. Buckingham.....................................131–3
Telephone Cable, Lightning Protection on the Stevens Point—Wisconsin Rapids Intercity. Dowling.... 697–701
Telephone Cable System—Planning and Over-all Performance, Transatlantic. Mottram, Halsey, Emling, Griffith..............................842–50
Telephone Carrier Frequency Networks. Wallenstein. 691–7
Telephone Circuits, Recent Developments in 4-Wire Switching of Long-Distance. Molnar........... ....722–32; disc. 732
Telephone Companies, Microwave for. Fisher..538–42
Telephone Lines, Application of the Type-P1 Carrier System to Rural. Howard.....205–13; disc. 214
Telephone Service, A 72-Channel Radio System for Toll. Harp, Kebby............113–19; disc. 119
Telephone Sets, Transmission Rating of. Johnson, Eppes........................646–52; disc. 652
Telephone Signaling Circuit Performance, Influence of Noise on. Weber..........................636–42
Telephone Switching Systems, Electronics in. Joel.... ....701–09; disc. 710
Teletypewriter Lines, Automatic Dispatch System for Half-Duplex. Maxwell, Farrar..............441–5
Teletypewriters, Static Elimination on Bell System. Bavley, Perry, Swezey.................... 92–4
(Television) A Video Visual Measuring Set with Sync Pulses. Sproul...........................427–32
Television, Conversion of Studio Lighting from Black and White to Color. Wygant...............75–8
(Television) Field Experience with the A2A Video System. Gast...............................710–16
Television System Performance Requirements, Color-. Kennedy...............................653–9
Temperature Stabilization of Transistor Amplifiers. Vallese.................................379–84
Tensor of the General Machine, The Impedance. Yu. 181–7
Test on 955.5 Mc, 1,965 Mc, and 6,700 Mc, Propagation. Mathwich, Nuttall, Pitman, Randolph.... 685–91
Theory: Head Design, Magnetic Data Recording. Hoagland.....................................506–12
Theory, The Communication Engineer's Needs in Information. Rea...........................805–08
Thin Rectangular Plate, Accurate Determination of the Capacitance of a. Reitan, Higgins..761–6; disc. 766
Thin-Wire Loop Antennas, Impedance of. Storer.... 606–18
Three Common Emitter Transistor Servo Preamplifiers, A Comparison of. DeSautels..............17–25
Three-Phase Magnetic Amplifier, Dynamic Behavior of a. Ellert..................554–60; disc. 560
Time-Division Multiplex Telegraph Set, A Transistorized. Biggam..............................780–5
Time Underfrequency Relay, Inverse-. Hoft...625–9
Titanate Ceramics, Investigations Concerning Polarization in Barium. Marks, Waidelich, Monson...... 469–77
Toll Telephone Service, A 72-Channel Radio System for. Harp, Kebby..............113–19; disc. 119
Toroidal Cores Used in Magnetic Amplifiers, Low-Impedance Operational Characteristics of. Boyajian.......................................307–13
Traffic Considerations in Community Dial Offices. Lanigan, McDonough...........543–7; disc. 547
Transatlantic Cable System, Electron Tubes for the. McNally, Metson, Veazie, Holmes........898–907
Transatlantic Cable System, Route Selection and Cable Laying for the. Jack, Leech, Lewis......944–55
Transatlantic Communications: A Historical Résumé. Kelly, Radley..............................841–2
(Transatlantic) Power-Feed Equipment for the North Atlantic Link. Meszaros, Spencer........890–8
(Transatlantic) Power-Feed System for the Newfoundland–Nova Scotia Link. Thomas, Kelly...938–43
(Transatlantic) Repeater Design for the Newfoundland–Nova Scotia Link. Brockbank, Walker, Welsby.. 927–38
(Transatlantic) Repeater Design for the North Atlantic Link. Gleichmann, Lince, Wooley, Braga..865–77
(Transatlantic) Repeater Production for the North Atlantic Link. Lamb, Heffner.............877–89
Transatlantic Submarine Cable System, Cable Design and Manufacture for the. Lebert, Fischer, Biskeborn..907–17
(Transatlantic) System Design for the Newfoundland–Nova Scotia Link. Halsey, Bampton.....917–27
(Transatlantic) System Design for the North Atlantic Link. Lewis, Tucker, Lovell, Fraser......850–64
Transatlantic Telephone Cable System—Planning and Over-all Performance. Mottram, Halsey, Emling, Griffith..842–50
Transcendental Function Analogue Computation with Magnetic Cores. Schaefer, Van Allen........... ....160–4; disc. 164
Transcontinental Communications in Canada, Development of. Noyes, Gaudet, Bonneville......342–52
Transducers for the Reproduction of Physiological Phenomena, Physical Response Requirements of Pressure. Wood.......................................32–40
Transfer Functions with Poles Restricted to the Negative Real Axis into Two Parallel R-C Ladders and an Ideal Transformer, Synthesis of. Malti, Sun...... ....165–71; disc. 171
Transformer Oil Quality, A Field Survey of. Degnan, Shimanski......................575–9; disc. 579
Transformer Reactance Calculations with Digital Computers. Rabins.................261–7; disc. 267
Transformer, Synthesis of Transfer Functions with Poles Restricted to the Negative Real Axis into Two Parallel R-C Ladders and an Ideal. Malti, Sun..........................165–71; disc. 171
Transformers, Multiunit Neutralizing. Palmquist..... 717–21
Transformers to Specification, Application of a Digital Computer to the Design of Power. Moore, Duboc, Zaphyr..........................134–7; disc. 137
Transformers Utilizing a Synthesized Equivalent Network, Design of Wide-Band R-F. Kajihara.802–05
Transistor Amplifiers, Temperature Stabilization of. Vallese...................................379–84
Transistor Analogue Computing Amplifiers for Flight Simulators. Weyrick......................338–42
Transistor Applications, Field Effect. Huang, Marshall, White..................................323–9
Transistor as a Bilateral Switching Element, The Symmetrical. Trousdale.....................400–03
Transistor Audio Amplifiers, Optimum Design of Common-Emitter. Vallese......................391–5
Transistor Flip-Flops, D-C Graphical Analysis of Junction. Bashkow..............................1–7
Transistor Magnetic-Coupled Oscillator, A Single-. Chen, Schiewe................396–9; disc. 400
Transistor Power Amplifiers with Switched Mode of Operation. Milnes..........................368–72
Transistor Power Supply, Magnetic Regulation. Lyons..643–5
Transistor Servo Preamplifiers, A Comparison of Three Common Emitter. DeSautels.............17–25
Transistor Switching Circuit, Power. Huang, Slobodzinski.......................................290–6
Transistor Voltage Regulator. Spencer, Gray..15–17
Transistorized Time-Division Multiplex Telegraph Set, A. Biggam...............................780–5
Transistors, A New 4-Channel Open-Wire Carrier System Employing. Caruthers, Chaskin, Krengel... 314–22
Transistors, Magnetic Amplifier Control of Switching. Collins...................................585–9
Transistors to Carrier-Frequency Computing Amplifiers, Application of Junction. Curtin.............. ....746–52; disc. 752
Translating Languages by Machine, The Technical Feasibility of. Yngve.........................792–7
Translation of Language, Some of the Engineering Aspects of the Machine. Wall..580–4; disc. 585
Transmission Machine, A Data. Doty, Tate...600–03
Transmission of Business Machine Data Over Standard Telegraph Channels. Bramhall..416–20; disc. 420
Transmission Rating of Telephone Sets. Johnson, Eppes.........................646–52; disc. 652
Transmission System, Application of Statistical Techniques to Electron Tubes for Use in a 4,000-Mile. Van Haste..50–4
Transmitter, A Flat-Bed Facsimile Telegraph. Buckingham.....................................131–3
Triductor, The. Biringer............590–3; disc. 593
Trigger Pair, An Analysis and Design of the Ferroelectric Resonant. Gremer..................404–07
Trigger Pair: Analysis and Design, The Ferroresonant. Spitzer..................................407–16
Tube, Method of Measuring Spot Size of Cathode-Ray. Kuhn, Levine..................357–9; disc. 359
Two New Total Radiation Pyrometers. Derganc, Howell..360–7
2-Phase Motor Load, Measurements on High-Speed Magnetic Servo Amplifiers with. Geyger..242–8
Type-P1 Carrier System, Circuit and Equipment Descriptions of. Eberhart, Hallenbeck, Perkins..... 195–204
Type-P1 Carrier System, Objectives and General Description of the. Boyd....................188–91
Type-P1 Carrier System, Power Supplies for the. Smith..........................191–4; disc. 194
Type-P1 Carrier System to Rural Telephone Lines, Application of the. Howard....205–13; disc. 214

U

Underfrequency Relay, Inverse-Time. Hoft....625–9
Units and Dimensions, Electrical. Young........... ....767–8; disc. 768

D-C Graphical Analysis of Junction Transistor Flip-Flops

T. R. BASHKOW
NONMEMBER AIEE

THE D-C analysis and design of nonlinear circuits may be greatly facilitated by graphical means. A graphical approach, if it is simple enough, seems to have the happy faculty of providing understanding of existing circuit operation and hints for better or different designs. This has been amply illustrated recently by the wide use of a negative resistance curve for point contact trigger circuits.

A graphical analysis of the circuit of Fig. 1 has therefore been developed. This circuit, or variations thereof, has been analyzed previously[1] by straightforward algebraic methods assuming one transistor is ON and the other OFF. The resulting set of relations among the various parameters is then used to insure that the initial assumptions are satisfied.

The analysis to be presented makes no initial assumptions as to the d-c state of the circuit. Instead, a modification of the conventional graphical technique of plotting a load line on a set of device characteristics is used. In this case, however, two load lines are required, except that only one is needed for a completely symmetrical circuit. Since the load lines include all possible d-c operating points they must include the location of the d-c stable points as well. A variation in any of the circuit parameters produces observable changes in the stable points and thus bistability or, if desired, monostability can be attained.

The method is not exact, because a linearization of transistor characteristics is made, but experimental checks on the results have been quite good. As with all graphical methods, this one shows a change in resistance or voltage as a change of slope or intercept of straight lines and is therefore amenable to use as a design technique; see example in the Appendix.

General Description of Method

The following analysis can be generally applied to any circuit of this type whether the active element be transistor or vacuum tube, but for illustration only *p-n-p* junction transistors will be used. The approach is to consider one part of the circuit as isolated and the rest of the circuit as a single load. (The labeling of Fig. 1 reflects this in that R_2, R_c, R_1 and the base-to-ground resistance of T_b are the load for T_a. The load for T_b is R_2', R_c', R_1', and the base-to-ground resistance of T_a.) The isolated circuit is that shown in Fig. 2(A). Plotting V_2 versus I_2 the usual collector characteristics of T_a, is obtained, modified by R_2, E and V_{cc}, shown in Fig. 2(B). The conventional drive current, I_b', is here labeled in terms of I_1'. If $R_1' \rightarrow \infty$ these, of course, are identical.

The load for the circuit of Fig. 2 is given in Fig. 3(A). Note that $I_2=-I_1$. This load consists of R_c in series with the parallel combination of R_1 and the input resistance of T_b. When T_b is ON, the load is $\cong R_c$; when T_b is OFF the load is $\cong R_c+R_1$. In Fig. 3(B), the dashed line represents the parallel combination of R_1 and the base-to-ground resistance of T_b. The solid line, the actual load line, results when R_c is added graphically.

If the load line of Fig. 3(B) is plotted on Fig. 2(B), Fig. 4(A) results and, assuming the same procedure for T_b the result is Fig. 4(B).

The load lines of Fig. 4 consist of all possible d-c operating points for this circuit. The end points of the load lines, points 1 and 2, are the two stable points required for a bistable circuit. To indicate that this is so, consider that T_b is OFF, operating at point 1B. Reading the current co-ordinate of this point shows that $-I_1'$ is sufficient to turn T_a ON. Therefore T_a must be ON at the point *1a*. Reading the current co-ordinate of this point it is seen that $-I_1$ is not sufficient to turn T_b ON. Therefore, T_b must be OFF at the point *1b*. This is the starting point and the circuit is stable with T_b OFF, T_a ON.

Similarly it is seen that a second stable point must be at 2 with T_b ON, T_a OFF. Later, it will be shown that one of the stable points may lie in the active, rather than the saturated, region. A third possible operating point requires both transistors to be in their active region. (All three operating points are d-c stable. It is fairly obvious that the two d-c stable points of Fig. 4 are also dynamically stable since the OFF transistor opens the feedback loop. Dynamic stability of the third point must be investigated by methods outside the scope of this presentation.)

In the next sections specific information is given concerning the modified collector family and the d-c load line. It will be shown that these can easily be drawn with a knowledge of circuit parameters and a few transistor parameters.

Modified Collector Family

For the *p-n-p* transistor circuit of Fig. (5A)

$$I_2=\frac{V_2-V_{cc}}{R_2}+I_c \qquad (1)$$

may be written as the equation for the currents at the collector node.

For $I_c=0$, T_a is cut off, and $I_2=(V_2-V_{cc})/R_2$ which is plotted as the line of slope R_2 connecting the points $I_2=-V_{cc}/R_2$ and $V_2=V_{cc}$ of Fig. 5(B). Since I_c does not go to zero under normal conditions this cutoff line represents a limit rather than an actuality, but is approached very closely with a slightly positive value of I_b'. (As would be expected, the minimum value of I_c depends very strongly on I_{co} and as $|I_{co}|$ increases, the actual cutoff line moves further from this limit.)

For $V_2=E$, the transistor is in saturation and presents a low resistance r. For this condition, if, in addition, $I_c=0$, the intersection is obtained of saturation and cutoff lines at $V_2=E$, $I_2=(E-V_{cc})/R_2$, as shown in Fig. 5(B).

The lines of constant I_1' in the active region of Fig. 5(B) may also be considered to be of slope R_2. This is, of course, not strictly true because of the finite collector resistance, but experimental results indicate that it is a good approximation. The reason is twofold: 1. R_2 shunts the collector resistance $(1-\alpha)r_c$. If R_2 is much smaller than $(1-\alpha)r_c$, it is the only effective resistance; 2. If R_2 is increased, holding V_{cc} constant, the collector current I_c decreases. As shown by Early,[2] this causes an increase in r_c and allows the condition $R_2<<(1-\alpha)r_c$ to be maintained.

Paper 56-24, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted July 26, 1955; made available for printing November 10, 1955.

T. R. BASHKOW is with the Bell Telephone Laboratories, Inc., Murray Hill, N. J.

LOAD LINE FOR Ta
(B)

Fig. 3. Load line for T_a and portion of circuit from which it is obtained

Since the characteristic curves in the active region are straight lines of slope R_2 it is only necessary to find their intercepts, for each value of I_1'.

For the intercept at $I_2=0$ it is clear from equation 1 that $V_2=V_{cc}-I_cR_2$. Since

$$I_c=\frac{\alpha_n}{(1-\alpha_n)}I_b'+\frac{I_{c0}}{1-\alpha_n}$$

for each value of I_b', for a given transistor, the intercept can be found and, with the slope known, the corresponding line in the active region can be plotted. However, it is required that these lines be labeled in terms of I_1' and thus a relationship between I_1' and I_b' is needed. From Fig. 5 it is seen that

$$I_1'-\frac{V_1'}{R_1'}=I_b'$$

but I_b' is also dependent on V_1' so this equation must be solved graphically. It is apparent, however, that I_1' must be more negative than E/R_1' in order to overcome the emitter bias E and get the transistor out of cutoff. Increasingly negative values of I_1' move the transistor into the active region and eventually into saturation.

The modified collector family can thus be drawn from a knowledge of V_{cc}, R_2, E, and the saturation slope, which is a measurable constant for a given transistor. To label the curves in terms of I_1', it is necessary to measure I_{c0} and α_n. The relationship between I_b' and I_1' as well as an illustrative example are given in the Appendix.

Load Line

For the circuit of Fig. 6 $V_2=V_1-I_2R_c$ may be written or, since $I_2=-I_1$

$$V_2=V_1+I_1R_c \tag{2}$$

Equation 2 may be solved by plotting V_1 versus I_1 and adding I_1R_c graphically.

A linearized plot of V_1 versus I_1 for a *p-n-p* transistor is shown in Fig. 7(A) and 7(B) for two values of E. When the transistor is OFF, the base-to-ground resistance is very high and the external base resistance R_1 relates V_1 to I_1. When the transistor is ON, the low resistance r_T shunts R_1. The effect of emitter bias is simply to cause a translation of the zero bias curve of Fig. 7(A) by E along the voltage axis and E/R_1 along the current axis. The current I_T and the slope r_T are constants for a given transistor and must be measured. (That I_T is a transistor constant, independent of R_1, may seem strange until it is realized that at $I_1=I_T$, $V_1=0$. With an effective dead short from base to ground it is immaterial what resistance is connected from base to ground.) Fig. 7 shows no dependence on I_2', the current into the collector node of T_b. This is to be expected of any unilateral device. It is true of a *p-n-p* transistor as long as $I_2'<-V_{cc}/R_2'$, which keeps the collector junction in its normal state of reverse bias. This condition on I_2' holds under normal circuit operation.

Having V_1 versus I_1 the desired load line may now be obtained by adding I_1R_c to each value of V_1. Since I_1R_c is just a line of slope R_c, it may be added

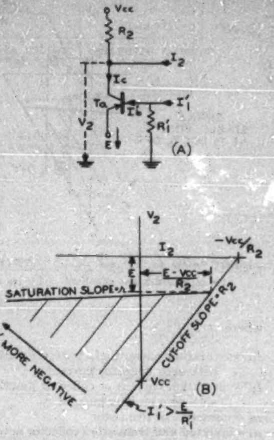

Fig. 5. Slopes and intercepts of modified collector family for T_a in terms of circuit parameters

graphically to the V_1, I_1 curve by the constructions shown in Fig. 8, which has been greatly exaggerated for clarity. The resulting broken line, shown solid in Fig. 8, is the desired load line. The construction is quite simple.

1. Pick any point on the V_1-I_1 curve.
2. At this value of V_1, on the voltage axis, draw a line of slope R_c.
3. The intersection of this line with the initial value of I_1 which was chosen gives one point on the load line.

Actually, only three points need be chosen, one point in the OFF region, one in the ON region, and the break point between them. As a check, the load line should intersect the V_1-I_1 curve at $I_1=0$, since for this case $V_2=V_1$ according to equation 2.

The modified collector curves are plotted as V_2 versus I_2 and the load line of Fig. 8 is plotted as V_2 versus $-I_2$. The latter must therefore be rotated about the voltage axis to obtain Figs. 3(B) and 4(B).

The load line can thus be drawn from a knowledge of R_1, R_c, E, and the simple construction of Fig. 8. In addition, the transistor constant I_T (which is of the order of I_{c0}) is needed and the ON base-to-ground resistance r_T, both of which must be measured; see the Appendix.

Use of Method

It should be emphasized that the simplification used in deriving the load line, e.g., that the transistor goes abruptly from ON to OFF at a critical value of I_1 is, of course, a fiction. It is obvious from the modified collector curves that there is a range of I_1 over which the transistor goes from ON to OFF. The α of the transistor is of particular importance in determining how closely the reality of transistor operation corresponds to the fiction. For precise design the method of the Appendix for relating I_1 to I_b (or I_1' to I_b') and labeling the modified collector characteristic must be followed. However, for a qualitative understanding of circuit action the simplification is quite useful and will be adhered to in the following discussion. This analysis provides results in the form of two graphs as shown in Fig. 9.

The two load lines contain all possible d-c operating points of the circuit and in particular the two end points are d-c stable points as explained earlier. However, suppose that R_1' is decreased so as obtain Fig. 10. In this case the circuit can never have a stable point with T_b OFF, T_a ON. To indicate this, assume that T_b is OFF; see Fig. 10(B). Reading the current co-ordinate of this point it is seen that $-I_1'$ is not sufficient to turn T_a ON. Therefore T_a must be OFF; see Fig. 10(A). Reading the current co-ordinate of this point it is seen that $-I_1$ is sufficient to turn T_b ON. Therefore T_b must be ON; see Fig. 10(B). However, this contradicts the initial assumption. Therefore the d-c condition of T_b OFF and T_a ON cannot exist. A similar analysis for T_b ON, and T_a OFF gives consistent results for both graphs simultaneously and is therefore the only d-c stable point. Fig. 11 shows another monostable circuit in which both transistors are OFF.

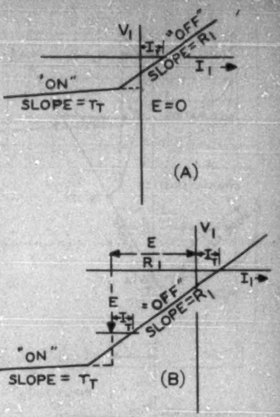

Fig. 7. Plot of voltage versus current (V_1 versus I_1), at base of T_b, for two values of emitter bias

For the following discussion a completely symmetrical circuit will be assumed, $R_1=R_1'$, $R_2=R_2'$, $R_c=R_c'$, T_a identical to T_b. In this case both graphs are identical. Only one need be drawn as in Fig. 12 which also shows the effect of a change in R_c. Assume that T_a is OFF, T_b ON. As R_c is increased, only the load line is affected. The OFF stable point then moves so that the current $-I_1$, keeping T_b ON, is decreased. In other words, T_b is coming further out of saturation. Eventually, T_b does not have enough base current to remain ON and both transistors are OFF. The two load lines whose OFF points are on either side of the dashed vertical line in Fig. 12 bracket a critical value of R_c, which allows bistability. A value of R_c slightly lower than this allows one transistor to be off

and the other to be on, but not saturated. A slightly higher value of R_c does not support bistability. A study of Fig. 12 and previous figures makes it evident that increasing R_2, making E more negative, decreasing R_1, or decreasing V_{cc} causes a similar effect to that just described for increasing R_c. It is therefore possible to design a bistable circuit which does not saturate, without using any additional circuit elements. Such a design would require rather close tolerances on components, and so seems impractical, but is mentioned to indicate a possible use of these graphs.

Other information also apparent on the graph is: 1. Voltage swing of collector, 2. Current through ON transistor, and 3. Voltage at base of OFF transistor. These conditions are illustrated in Fig. 13.

Some additional information, such as the effect of changes in α or I_{c0}, can also be obtained. However, these require more detailed analysis, such as that given in the example in the Appendix, and will not be given here.

Conclusions

The graphical analysis provides a picture from which the operation of a junction transistor bistable circuit can be understood by inspection. Since all circuit parameters appear explicitly, it becomes an easy matter to predict the effect of circuit variation on such things as collector voltage swing and maximum collector current. Furthermore, it is apparent whether or not the circuit values chosen will work at all, i.e., whether bistability can exist. The proper changes in parameter values to insure bistability can then be made and since the required graphs are simple to construct many possible designs can be tried in a short time.

Appendix. Relationships, Examples, and Measurements

Relationship between I₁ and I_b (or I₁′ and I_b′)

From the general expressions for alloy junction transistors given by Moll and Ebers[3] the following expression can be derived for I_b.

$$I_b=\frac{(1-\alpha_n)I_{e0}}{1-\alpha_n\,\alpha_i}\left(e^{-\frac{(V_1-E)}{0.026}}-1\right)-\frac{(1-\alpha_i)\,I_{c0}}{1-\alpha_n\,\alpha_i} \tag{3}$$

where

I_{e0} = saturation current of emitter junction with zero collector current
I_{c0} = saturation current of collector junction with zero emitter current
α_n = normal α of transistor
α_i = inverted α of transistor (collector acting as emitter, emitter acting as collector)
$kT/q \cong 0.026$ volts at room temperature

Equation 3 describes an exponential curve which can be plotted for a given transistor once the four transistor constants are known. (At the end of the Appendix some simple measurements for obtaining these transistor parameters are described.) The form is that of Fig. 14. Fig. 15 shows plots of equation 3 for two transistors with parameters as indicated and $E=0$. It is seen now that the I_T given as a constant for the V_1, I_1 approximation in the text is $-(K_1+K_2)\cong -K_2$.

The equation

$$I_1-\frac{V_1}{R_1}=I_b$$

can now be used to obtain the desired relation between I_1 and I_b. In the V_1, I_1 plane the left-hand side, I_1-V_1/R_1, is simply a line of slope $-R_1$ displaced along the current axis by I_1. The right-hand side is the previously determined curve for I_b. The graphical method of solution is therefore as shown in Fig. 16(A).

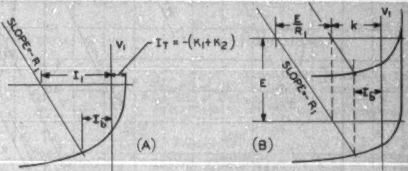

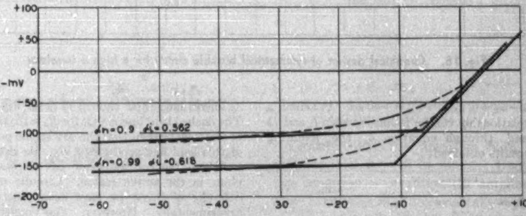

Fig. 17. Plot of V^1 versus I_1, $R_1=10{,}000\Omega$, for a high α and a low α transistor. Dotted curves are theoretical, solid curves are broken line approximations

This shows clearly why all V_1-I_1 plots go through the point I_T at $V_1=0$, regardless of the value of R_1. Fig. 16(B) shows that if $I_1=k$ for a given I_b with $E=0$, then $I_1=E/R_1+k$ for the same value of I_b. Fig. 17 shows a V_1-I_1 plot for $R_1=10{,}000\Omega$ with the curves of Fig. 15. The dashed lines are solutions of $I_1-V_1/R_1=I_b$, the solid lines are the suggested linear approximations.

Examples of Method as Design Technique

Assume a symmetrical circuit for which $V_{cc}=-5.9$ volts, $E=-1.5$ volts, $R_1=R_1'=10{,}000\Omega$ $R_2=R_2'=10{,}000\Omega$. It is desired to find a value of $R_c=R_c'$, which just insures a bistable circuit. This is not necessarily a realistic problem but will illustrate the graphical method and associated calculations.

Case I: High α Units

The load line and modified collector family are given in Fig. 18(A). The load line was constructed using $R_c=15{,}000\Omega$ and the lower solid curve of Fig. 17. This value of R_c was chosen so that the OFF stable point is just beyond the "break" point of the V_1, I_1 curve, $-I_1=-E/R_1+20\mu a=170\ \mu a$.

To check this design the lower curve is used of Fig. 15 (from which the lower solid curve of Fig. 17 was obtained). From the graphical method of the previous section the following relationship is obtained between I_1 and I_b:

I_1	I_b
+ 5.0 μa	+4.0 μa
+ 0.0 μa	+3.7 μa
− 5.0 μa	+2.7 μa
−10.0 μa	0.0 μa
−15.0 μa	−3.2 μa

To find the $I_2=0$ intercept of the lines, I_1=constant, in the active region of the modified collector family, the following relation is used

$$V_2=V_{cc}-I_cR_2=V_{cc}-\left[\frac{\alpha_n}{1-\alpha_n}I_b+\frac{I_{c0}}{1-\alpha_n}\right]R_2 \quad (4)$$

For this transistor $\alpha_n/1-\alpha_n=0.99/0.01=99$, $I_{c0}/1-\alpha_n=-400\ \mu a$. The following table summarizes the numerical results.

I_1, μa	I_c, μa	$-I_cR_2$, volts	V_2, volts
+ 5.0	− 4*	+0.04	−5.86
+ 0.0	− 34	+0.34	−5.56
− 5.0	−132	+1.32	−4.58
−10.0	−400	+4.00	−1.90
−15.0	−716	+7.16	+1.26

* It can be shown that this minimum value of $I_C=\frac{1-\alpha_I}{1-\alpha_N\alpha_I}I_{c0}$. This value determines how closely the ideal cutoff line may be approached. It is seen that an increase in $|I_{c0}|$ causes a shift of the entire collector family to the left.

These lines are shown in Fig. 18(B). It can be seen that the graphical solution for $R_c=15{,}000\Omega$ of Fig. 18(A) is indeed proper to produce bistability since the OFF stable point at $-I_1=170\ \mu a$ is sufficient to drive the ON transistor well into saturation.

Case II: Low α Units

The modified collector family and load line for $R_c=15{,}000\Omega$ are given again in Fig. 19(A). This was constructed using the upper solid curve of Fig. 17. There is only a slight difference from Fig. 18(A) and the OFF stable point is still at $-I_1=170\ \mu a$.

This design will now be checked, with the upper curve of Fig. 15 for which $\alpha_n/$

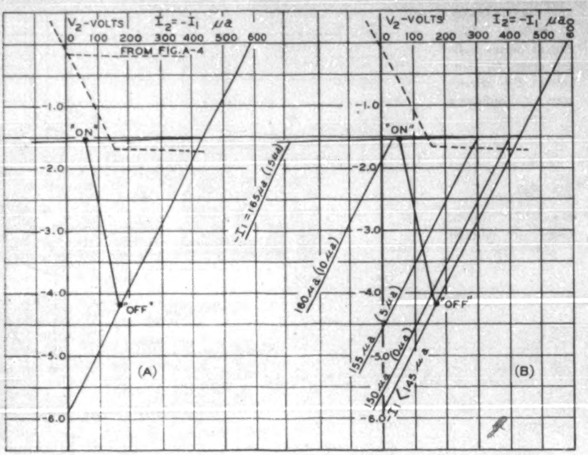

Fig. 18. Graphical design of symmetrical bistable circuit for a high α transistor

$1-\alpha_n=0$, $I_{c0}/1-\alpha_n=-40\ \mu a$. As before, a relationship can be found between I_1 and Ib and, through equation 4, the following results obtained:

I_1, μa	I_b, μa	I_c, μa	$-I_cR_2$, volts	V_1, volts
+ 5.0	+ 4.06	− 3.5	+0.04	−5.86
+ 0.0	+ 2.7	− 15.9	+0.16	−5.74
−20.0	−11.4	−142.5	+1.42	−4.48
−40.0	−29.4	−304.0	+3.04	−2.86
−60.0	−48.0	−472.0	+4.72	−1.18

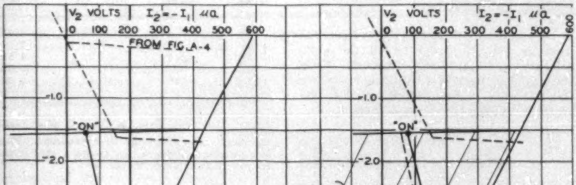

Fig. 19. Graphical design of symmetrical bistable circuit for a low α transistor

These lines are shown in Fig. 19(B). The dashed load line is that for $R_c=15{,}000\Omega$. It can now be seen that the OFF stable point of this load line produces a bistable circuit in which the ON transistor has its stable point in the active region. Circuits with behavior of this type have been observed experimentally. However, the collector voltage swing is not the maximum available and they are so sensitive as to swing very easily from one state to the other.

To obtain the maximum voltage swing and decrease trigger sensitivity, the solid load line of Fig. 19(B) for $R_c=10{,}000\Omega$, can be used. This value of R_c was chosen to have an OFF stable point at $-I_1=210\ \mu a$ which is sufficient to put the ON transistor into saturation. If it is desired to keep $R_c=15K$, one can increase R_1 or make E less negative instead.

It is apparent that this latter design, with $R_c=10{,}000\Omega$ may also be used for transistors with $\alpha_n>0.9$. The only difference is that the ON unit goes deeper into saturation. This particular design was checked in the laboratory using transistors with $\alpha_n=0.989$ and 0.944 respectively. From Fig. 19(B) the following can be read:

	V_2, volts	V_1, volts	I_1, μa
ON	−1.55	−0.8	− 75
OFF	−3.75	−1.65	−210
Measured Values			
ON	−1.55	−0.83	− 68
OFF	−3.8	−1.63	−200

Suggested Measurements on Transistor

For the circuit of Fig. 20, with the results of reference 3, it can be shown that for $V_1=0$, (base short-circuited to ground)

$$I_b=\frac{-(1-\alpha_i)I_{c0}}{1-\alpha_n\alpha_i}$$

$$I_c=\frac{I_{c0}}{1-\alpha_n\alpha_i}$$

and for $I_b=0$, (base open-circuited)

$$I_c=\frac{I_{c0}}{1-\alpha_n}$$

For these measurements the voltage at the collector should be kept at least slightly negative, −0.5 volt for a *p-n-p* transistor, otherwise the assumptions used in deriving these results are invalidated. With the relations

$$\frac{\alpha_n}{1-\alpha_n}=\frac{\dfrac{I_{c0}}{1-\alpha_n\alpha_i}-\dfrac{I_{c0}}{1-\alpha_n}}{\dfrac{-(1-\alpha_i)I_{c0}}{1-\alpha_n\alpha_i}}=\alpha'$$

or

$$\alpha_n=\frac{\alpha'}{1+\alpha'}$$

$$\alpha_i=1+\frac{\dfrac{-(1-\alpha_i)I_{c0}}{1-\alpha_n\alpha_i}}{\dfrac{I_{c0}}{1-\alpha_n\alpha_i}}$$

$$\alpha_nI_{e0}=\alpha_iI_{c0}$$

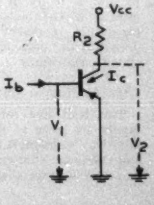

Fig. 20 (right). Circuit used for measurement of transistor parameters all transistor parameters can be obtained from the suggested measurements. (Any convenient measuring equipment can, of course, be used to obtain these parameters. This method recommended itself because two of the measurements are used directly in the calculations indicated previously. They do not depend on the accuracy of separate α and I_{c0} measurements.)

To illustrate, a set of measurements for a *p-n-p* transistor gave for $V_1=0$

$I_e=-13\ \mu a$
$I_b=+6\ \mu a$

and for $I_b=0$

$I_e=-260\ \mu a$

Therefore

$$\frac{\alpha_n}{1-\alpha_n}=\frac{-13+260}{6}=41.2$$

or

$$\alpha_n=\frac{41.2}{42.2}=0.976$$

$$\alpha_i=1+\frac{+6}{-13}=0.538$$

$$I_{c0}=-260(1-0.976)=-6.25\ \mu a$$

$$I_{e0}=\frac{0.538}{0.976}(-6.25\ \mu a)=-3.44\ \mu a$$

The circuit of Fig. 20 can also be used to obtain the slope r_T for the V_1, I_1 curves, and the saturation slope r. A current source large enough to saturate the transistor is required. Measurements on a *p-n-p* transistor gave

$V_1=-0.184$ volts for $I_b=-200\ \mu a$

$V_1=-0.167$ volts for $I_b=-100\ \mu a$

Therefore

$$r_T=\frac{0.184-0.167}{100\times 10^{-6}}=170\Omega$$

A measurement of V_2 at $I_b=-800\ \mu a$, ($I_2=0$, $E=0$) gave

$V_2=-33$ millivolts

We assume that $V_2=0$ at $I_2=-V_{cc}/R_2$. This measurement gave

$$I_2=\frac{5.9 \text{ volts}}{5,200}=1.135 \text{ milliamperes}$$

Therefore

$$r=\frac{33}{1.135}=29.1\Omega$$

Full-Wave Bridge Magnetic Amplifiers with Inductive Loads

H. H. WOODSON
ASSOCIATE MEMBER AIEE

THERE are numerous articles treating magnetic amplifiers with inductive loads.[1–4] In the majority of these papers the inductive loads are considered without so-called free-wheeling or discharge paths. When single-ended d-c output circuits are considered in the literature, the conditions are first derived for which the circuit will be unstable with no discharge paths;[1,3] then discharge paths are added to make the system stable. In the references cited, the discharge rectifiers are considered to have zero forward resistance, thereby achieving complete decoupling of the inductive load from the controlling reactors during the reset period.

The purpose of this paper is to investigate empirically the effect of discharge rectifiers, in which the forward resistance is assumed to be appreciable, on the operation of a single-ended amplifier with inductive load. An additional assumption is that the load has a time constant which is long compared to the period of the supply. The result of this study is presented in the form of a block diagram to facilitate the use of the results in feedback control system design and in design for which analogue computers are employed.

Resistive Load

The magnetic amplifier used in this study is the full-wave bridge circuit shown schematically in Fig. 1. The components for this circuit are listed in the following.

Reactors: 2-mil Orthonol $1^1/_2$ inches by $2^1/_2$ inches by 1 inch; $N_g=250$ turns no. 20 wire, $N_c=600$ turns no. 30 wire
RX = radio receptor selenium rectifiers, 26-volt cells, $1^1/_2$ inches by $1^1/_2$ inches, 6 cells in series
$R_c=2{,}050$ ohms including the resistance of $2N_c$
$R_L=190$ ohms
$L=32.4$ henrys
$\tau_L=L/(R_L+R_g)=0.153$ second
$v_g=120\sqrt{2}\sin 2\pi\, 400\, t$
R_g = apparent internal resistance of amplifier at full output = 22 ohms

Consider first the amplifier with a resistive load $L=0$ in Fig. 1. Under this condition of operation the amplifier may be represented incrementally by a gain and a first order lag[4]

$$\frac{\partial I_L}{\partial N_cI_c}=G(s)=\frac{K/R_L}{\tau_m s+1}\ \frac{\text{amperes (amp)}}{\text{amp-turn}} \qquad (1)$$

where

I_L = average load current
I_c = average control current
K = gain, volts per amp-turn
$\tau_m=(N_c^2/R_c)k_c$
R_L = load resistance
k_c = constant of the load circuit and reactors

The gain K is found at a certain output level from the steady-state transfer characteristic such as that given as curve A in Fig. 2. For this example, the output level is 0.2 amp and

$$K=0.250\ \frac{\text{volts}}{\text{amp-turn}} \qquad (2)$$

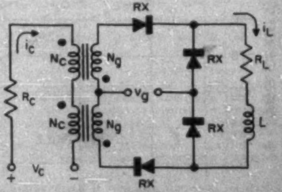

Fig. 1. Full-wave bridge magnetic amplifier circuit

Paper 56-9, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted August 2, 1955; made available for printing October 11, 1955.

H. H. WOODSON is with the Massachusetts Institute of Technology, Cambridge, Mass.

The research on which this paper is based was supported, in part, by the Department of the U. S. Air Force under Contract *AF 33(616)2669*.

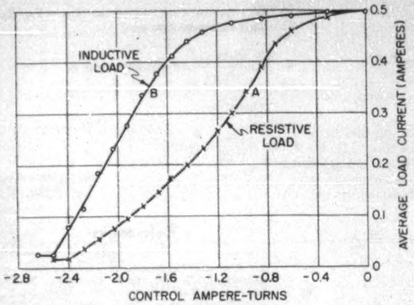

Fig. 2 (left). Steady-state transfer characteristics

The time constant τ_m is found from the frequency response curves A of Figs. 3(A) and (B)

$$\tau_m = 0.047 \text{ second} \qquad (3)$$

These constants will be used in the treatment of inductive loads to follow.

Inductive Load

An inductive load having a time constant which is very long compared to the period of the supply will have a continuous current flowing through it during the entire period of the supply voltage. Thus, during the intervals of time when both reactors are unsaturated, the load current will flow through both discharge rectifiers, as indicated by path A in Fig. 4. When one reactor is saturated, the load current will flow through only one discharge rectifier as indicated by path B or C in Fig. 4. In general, the same voltage drop v_f appears across both nonideal discharge rectifiers when they are conducting.

When the discharge rectifiers are assumed to have zero forward resistance, the voltage drops v_f disappear and the inductive load can have no effect on the unsaturated flux change in either reactor assuming that the saturated coupling between gate and control windings is negligible. Therefore, the load is decoupled from the reactors during the reset period and the incremental transfer function with inductive load becomes the product of the amplifier transfer function of equation 1 and the first-order lag of the inductive load

$$G'(s) = \frac{K/R_L}{(\tau_m s+1)(\tau_L s+1)} \ \frac{\text{amp}}{\text{amp-turn}} \qquad (4)$$

On the other hand, when the discharge rectifiers have appreciable forward resistances, the voltage drops v_f shown in Fig. 4 can affect the flux changes in the reactors. The voltage drops v_f will increase with increasing load current, and reference to Fig. 5 shows that these voltages tend to saturate the reactors. Therefore, the voltages v_f will cause a positive feedback which varies with the average load current I_L. This feedback can be represented by the feedback factor β shown in the block diagram of Fig. 5. In general, the factor β will not be a constant but will depend on the output level as well as on the circuit parameters.

The transfer function for the block diagram of Fig. 5 is

$$G''(s) = \frac{\dfrac{K'}{1-\beta K'}}{\dfrac{\tau_m \tau_L}{1-\beta K'}s^2 + \dfrac{\tau_m+\tau_L}{1-\beta K'}s + 1} \qquad (5)$$

where $K' = K/R_L$. From a plot of the steady-state transfer characteristic of the amplifier with inductive load the factor β can be determined as a function of output level. A transfer characteristic with inductive load is shown as curve B in Fig. 2. From a comparison of the slopes of the two curves of Fig. 2, the factor

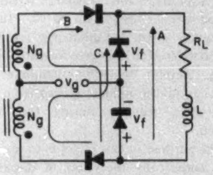

Fig. 4. Circuit showing load current paths

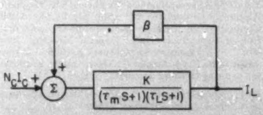

Fig. 5. Representation of feedback caused by nonideal discharge rectifiers

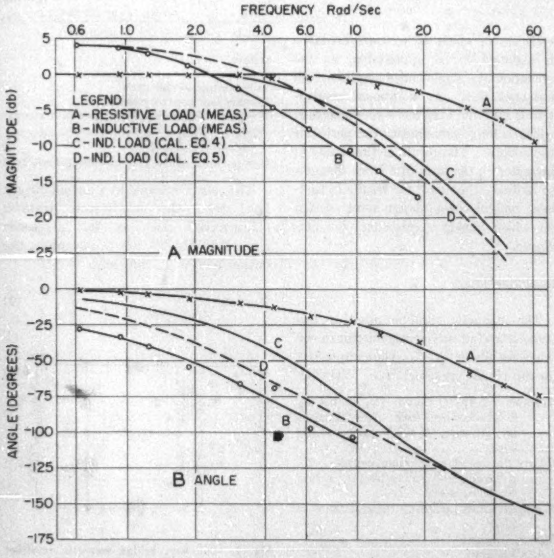

Fig. 3. Frequency response characteristics

Vol. 7
Pt. 1
1956

$(1-\beta K')$ is found at an output level of 0.2 amp to be

$$(1-\beta K')|_{I_L=0.2}=0.53 \qquad (6)$$

The frequency response for the circuit with the inductive load indicated in Fig. 1, for a small signal at an output level of 0.2 amp, is shown as curves B in Fig. 3. Two predictions are made for comparison. Curves C in Fig. 3 are predicted with the use of the approximation of perfect discharge rectifiers given in equation 4. Curves D are predicted with the use of the transfer function of equation 5 with the value of $(1-\beta K')$ found from the steady-state transfer characteristics and given by equation 6.

The results presented in Fig. 3 indicate that the addition of the positive feedback loop does not give absolutely accurate prediction of the experimental results; however, the accuracy indicates that such a feedback probably does occur but not wholly in the simple manner depicted. Nevertheless, the addition of the positive feedback loop does give results which can be useful in design work, especially with analogue computers.

Conclusions

The effect of nonideal discharge rectifiers on the dynamic operation of a full-wave magnetic amplifier with inductive load has been shown to be empirically describable as a nonlinear positive feedback. More detailed study is necessary to determine exactly how the feedback factor β varies with all the circuit parameters.

The problem of nonideal discharge rectifiers arises in connection with the application of selenium rectifiers. When silicon-junction rectifiers are used, this problem essentially disappears. However, in some cases, additional resistance be place in series with the discharge rectifiers to acquire special characteristics obtainable with the resulting nonlinear feedback.

The concept of a positive feedback to account for imperfect discharge rectifiers has been used to obtain an improved design for an aircraft alternator regulator. this concept proved especially useful in simplifying computer studies of the complete system.

Standing-Wave Ratio of Inaccessible Load

CHARLES POLK
ASSOCIATE MEMBER AIEE

Synopsis. Formulas are given for the minimum and maximum possible voltage standing-wave ratio (VSWR) of an inaccessible load fed by an imperfect transmission line. The formulas involve measurements at the accessible input terminals of the transmission line. Required data are the VSWR existing when the line is terminated by a known, perfectly matched load and the VSWR measured when the line is terminated by the unknown load.

WHEN a determination of the input VSWR of an antenna located on a high tower is required, it is frequently difficult to perform measurements directly at the antenna terminals. It is, however, possible to disconnect the antenna from the transmission line and to replace it, temporarily, by a load matched exactly to the nominal characteristic impedance of the line. Measurements can then be performed on the ground, at the input terminals of the transmission circuit.

It is thus possible to determine not only the VSWR (S) of the transmission line terminated by the antenna, but also the VSWR (S_1) of the transmission line terminated by a nominally matched load.

If S_1 is equal to one, the transmission circuit is perfect, or at least all reflections along the transmission line cancel each other at the input terminals. In this case one may assume that S is the actual VSWR of the antenna. Usually, however, $S_1 \neq 1$ indicating some imperfections along the transmission line which may be due to such causes as imperfect insulators, bends, joints, or transitions. The problem is then to deduce from S_1 and S the possible minimum and maximum values of the VSWR which would be measured directly at the antenna terminals.

While the present paper resulted from the antenna problem, the equations given are, of course, applicable to any analogous situation. The antenna may be replaced by any unknown load and the transmission circuit may consist, for example, of coaxial lines or wave guides. The frequency involved is assumed to be high enough for VSWR data to be of interest.

Attenuation is neglected in the present analysis and therefore the equations are strictly valid only if the transmission circuit has no dissipation loss. However, if the VSWR's of the system are small, small losses in the line will not account for any appreciable difference between the VSWR's measured at opposite ends of the transmission lines. For instance, compare reference 1, page 148: If the transmission-line dissipation loss is $^1/_2$ decibel (89-per-cent line efficiency), a 1.5 VSWR at the load termination will appear as a 1.432 VSWR at the input end.

Equations

Let

S = VSWR measured at the input terminals of the transmission circuit when the unknown load is connected to the far end

S_1 = VSWR measured at the input terminals of the transmission circuit when a perfectly matched load is connected to the far end. A perfectly matched load is one matched exactly to the nominal characteristic impedance of the transmission line at the measurement frequency

$S_{2\max}$ = maximum possible VSWR of the unknown load

$S_{2\min}$ = minimum possible VSWR of the unknown load

Paper 56-32, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted July 18, 1955; made available for printing November 15, 1955.

CHARLES POLK is with the University of Pennsylvania, Philadelphia, Pa.

The author wishes to express his appreciation to his colleague, Dr. P. P. Lombardini, for helpful discussions on the subject of this paper.

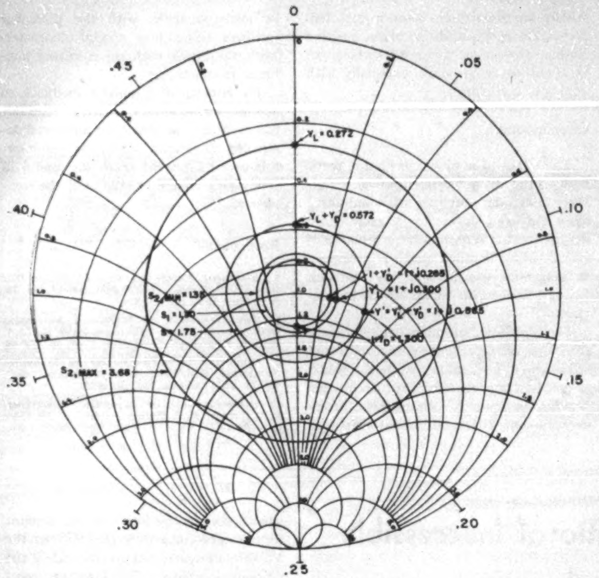

Fig. 1. Illustration of numerical example

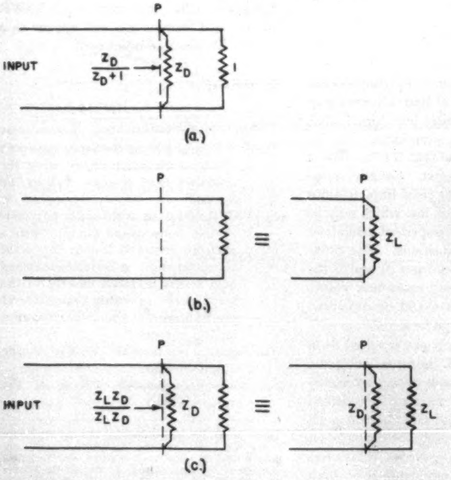

Fig. 2. Transmission-line circuit considered for the derivations of equations 1 and 2

When the conductor and dielectric losses in the transmission circuit are zero, the relations for $S_{2\max}$ and $S_{2\min}$ are

$$S_{2\max} = \frac{S}{S - SS_1 + 1} \quad SS_1 \leq 1 + S \qquad (1)$$

$$S_{2\min} = \frac{S}{S_1} \quad S > S_1$$

$$S_{2\min} = \frac{S_1}{S} \quad S < S_1 \qquad (2)$$

Equation 1 is exact while equation 2 is valid only for VSWR's less than about three. The nature of the approximation is indicated in the derivation.

Numerical Example

Standing-wave ratio measured at input terminals when the unknown load is connected to the transmission line, $S = 1.75$. Standing-wave ratio measured at input terminals when the transmission line is terminated by a perfectly matched load, $S_1 = 1.30$.

From equation 1

$S_{2\max} = 3.68$

From equation 2

$S_{2\min} = 1.345$

These results may be checked approximately by reference to the Smith-chart, Fig. 1. For convenience, admittances are considered on the Smith-chart rather than impedances.[2]

It is shown in the subsequent derivation that $S_{2\max}$ corresponds to real values of $Y_D = 1/Z_D$ and $Y_L = 1/Z_L$. Note that the matched load in parallel with the discontinuity gave a VSWR equal to 1.30, therefore $Y_D = 0.30$. The VSWR $S_{2\max} = 3.68$ found by equation 1 corresponds to a real admittance Y_L equal to 0.272. The sum of Y_L and Y_D is equal to 0.572 which corresponds to the measured standing-wave ratio $S = 1.75$.

To check $S_{2\min}$ assume Y_D as purely reactive; corresponding to $S_1 = 1.30$ $Y_D' = \pm$ j0.265 is obtained. When this Y_D' is placed in parallel with a load admittance $Y_L' = 1 \pm$ j0.30, corresponding to $S_{2\min} = 1.345$, $Y = 1 \pm$ j0.565 is obtained. This admittance corresponds again to the measured standing-wave ratio $S = 1.75$.

Derivation of Equations

The complex reflection coefficient $\Gamma = |\Gamma| \exp j\delta$ is defined as the ratio of the reflected to the incident wave. It is well known that the value of Γ at a point P on a transmission line of characteristic impedance K is given by

$$\Gamma = \frac{1-Z}{1+Z} \qquad (3)$$

where $Z = Z_T/K$ is the normalized value of the load impedance Z_T presented to the incident wave.[3]

In the following derivation all impedances are normalized. The impedance Z_D at point P in Fig. 2 represents the effective transmission-line discontinuity. If a matched load ($Z_T = K$) is connected to the line, the total input impedance at P becomes $Z_D/(Z_D+1)$ and, from equation 3, the complex reflection coefficient Γ_1 at point P, corresponding to this load, is given by

$$\Gamma_1 = \frac{1}{2Z_D+1} \tag{4}$$

Consider next the transmission line of Fig. 2 without the discontinuity ($Z_D=\infty$), but terminated by an unknown impedance, Fig. 2(b). The normalized value of this impedance, referred to point P, is Z_L. For this case the reflection coefficient at P is

$$\Gamma_1 = \frac{1-Z_L}{1+Z_L} \tag{5}$$

Finally, consider the line with the discontinuity and the unknown load impedance, Fig. 2(c). The reflection coefficient at P is now

$$\Gamma = \frac{Z_L+Z_D-Z_LZ_D}{Z_L+Z_D+Z_LZ_D} \tag{6}$$

Expressing Z_L in terms of Γ and Γ_1 by use of equations 4 and 6 and by substitution into equation 5, the following is obtained:

$$\Gamma_2 = \frac{\Gamma-\Gamma_1}{\Gamma\Gamma_1-2\Gamma_1+1} \tag{7}$$

The reflection coefficients Γ, Γ_1, and Γ_2 are complex numbers; thus, one may write

$$\Gamma_2 = \frac{|\Gamma|e^{j\alpha}-|\Gamma_1|e^{j\beta}}{|\Gamma\Gamma_1|e^{j(\alpha+\beta)}-2|\Gamma_1|e^{j\alpha}+1} \tag{8}$$

The square of the absolute value of Γ_2 is given by

$$|\Gamma_2|^2 = \frac{|\Gamma|^2+|\Gamma_1|^2-2|\Gamma\Gamma_1|\cos(\alpha-\beta)}{|\Gamma\Gamma_1|^2+4|\Gamma_1|^2+1-4|\Gamma||\Gamma_1|^2\cos\alpha - 4|\Gamma_1|\cos\beta+2|\Gamma\Gamma_1|\cos(\alpha+\beta)} \tag{9}$$

By taking the partial derivatives with respect to α and β and equating to zero, it is found that one of the following relations must be satisfied if Γ_2 is to assume an extreme value:

$$\begin{aligned} &\alpha=0, \quad \beta=0 \\ \text{or } &\alpha=\pi, \quad \beta=0 \\ \text{or } &\alpha=0, \quad \beta=\pi \\ \text{or } &\alpha=\pi, \quad \beta=\pi \end{aligned} \tag{10}$$

Substitution back into equation 9 gives:

$$\alpha=\pi,\ \beta=0 \quad |\Gamma_2|_{\max} = \left|\frac{|\Gamma|+|\Gamma_1|}{1-|\Gamma\Gamma_1|-2|\Gamma_1|}\right| \tag{11}$$

$$\alpha=\pi,\ \beta=\pi \quad |\Gamma_2|_{\min} = \left|\frac{|\Gamma_1|-|\Gamma|}{1+|\Gamma\Gamma_1|+2|\Gamma_1|}\right| \tag{12}$$

However, examination of equation 4 shows that β equal to π would require Z_D to be a real negative number. This is impossible if Z_D is a passive element. When $|\Gamma|<0.5$ and $|\Gamma_1|<0.5$, a physically realizable low value of $|\Gamma_2|$ is given by assuming $\alpha=\beta$ and $\cos\beta=|\Gamma_1|$. Substitution of these values of α and $\cos\beta$ into equation 9 leads to

$$|\Gamma_2|_{\min} \approx \left|\frac{|\Gamma_1|-|\Gamma|}{1-|\Gamma\Gamma_1|}\right| \tag{13}$$

To obtain the VSWR's corresponding to $|\Gamma_2|_{\max}$, equation 11, and $|\Gamma_2|_{\min}$, equation 13, note that

$$|\Gamma| = \frac{S-1}{S+1} \quad |\Gamma_1| = \frac{S_1-1}{S_1+1} \quad |\Gamma_2| = \frac{S_2-1}{S_2+1} \tag{14}$$

Substitution of equation 14 into equations 11 and 13 leads to equations 1 and 2.

Simplified Printing Telegraph Switching and Integrated Data Processing

J. B. BOOTH
ASSOCIATE MEMBER AIEE

R. H. KLICH
NONMEMBER AIEE

Synopsis: Receiving and transmitting printing telegraph equipment, whether used in the simplest or the most complex circuit, has generally required some form of auxiliary equipment for switching and remote control. In many cases this auxiliary equipment is complex, costly, and requires as much space and electric power as the controlled equipment. A new concept in printing telegraph switching equipment has been realized in the development of the Teletype model *28* typing unit which may be utilized to perform many electrical and mechanical functions for selective calling, remote control, integrated data processing, and other special functions.

THE MODEL *28* typing unit,[1] shown in Fig. 1, is a completely new instrument designed primarily for high-speed printing telegraphy. The unit is small in size, light in weight, and at a given speed of operational requires considerably less maintenance than normally recommended for apparatus of this type. This unit operates with greater ease and efficiency at 100 words per minute than conventional units at slower speeds.

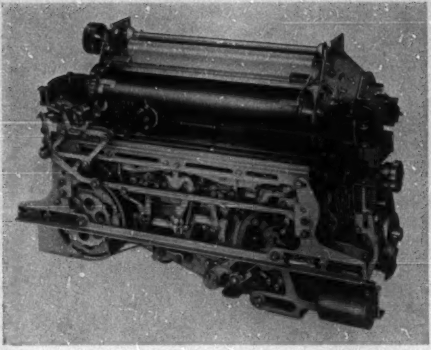
Every typing unit is equipped with a stunt box which controls the common functions, such as shifting the type box from lower to upper case, returning the printing carriage to the left-hand margin, line feeding, operating the signal bell, etc. In addition, the stunt box, as illustrated in Fig. 2, is capable of performing many electrical and mechanical functions.

The typing unit selector responds to a start-stop 5-unit (Baudot) signaling code consisting of current and no-current intervals, referred to as marking and spacing impulses, respectively. The selector mechanism of the typing unit converts these electric signals into mechanical motions which are transferred to a set of code bars to control the position of the type box for printing the received character, and to determine the function performed by the stunt box.

The stunt box, located directly behind the code bar assembly, has 42 slots, each of which will accommodate a function bar and its associated mechanism. These function bar mechanisms can be employed, in conjunction with the code bars, to initiate a mechanical or electrical action within the machine or at a remote location. Fig. 3 is a rear view of the typing unit with the stunt box removed to expose the code bar assembly.

Paper 56-28, recommended by the AIEE Telegraph Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted November 2, 1955; made available for printing November 14, 1955.

J. B. BOOTH and R. H. KLICH are with the Teletype Corporation, Chicago, Ill.



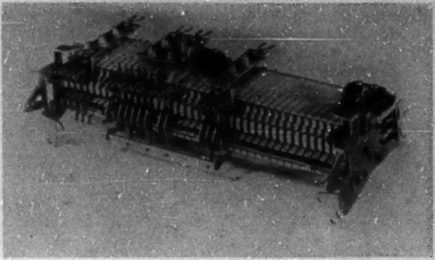


Fig. 1 (left). The model 28 typing unit

Fig. 2 (above). The typing unit stunt box

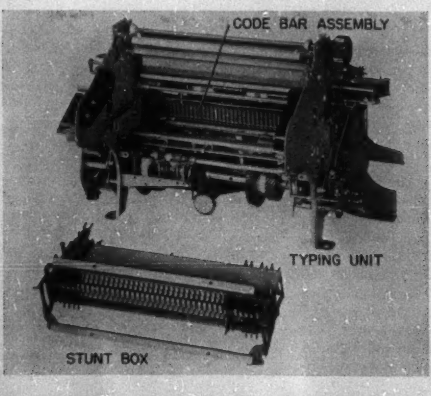
The code bars are moved to the left or right in response to marking or spacing elements of the Baudot code. A series of square notches extend across the rear of each code bar. The front of each function bar contains a series of tines which are formed to the left or right according to the marking or spacing pattern of the code combination to which the bar is to respond. The function bar-code bar relationship is illustrated in Fig. 4. The operation of any function bar mechanism is dependent upon the position of the code bars when sensed by the function bars. If the position of the code bar notches and function bar tines match, the function bar will enter the recessed portion of the code bar and condition the associated function bar mechanism for operation. The function bar, following its selection, is moved towards the rear of the typing unit performing a function dependent upon the arrangement of its associated mechanism. To change the code combination of any position in the stunt box only requires changing the function bar. The stunt box is readily removable to facilitate this change.

A simplified approach to many of the problems of switching and control is now possible using the model *28* typing unit. Usage in such applications as selectively calling stations in telegraph networks and integrated data processing are described.

Selective Calling of Model 28 Page Printer Sets

Many teletypewriter networks are equipped to permit stations selectively to call one another. This operation, referred to as selective calling, may be accomplished in many ways. Some systems utilize discrete telegraph characters to select the desired stations, some employ pulse duration or pulse coincidence signal coding, while others use frequency or tone keying. Regardless of the method used, the selection of teletypewriter stations has generally required some form of auxiliary control apparatus. The model *28* selective calling typing unit utilizes discrete telegraph characters, and requires no auxiliary control apparatus.

A review of the present usage of the Baudot code, as related to teletypewriters, will aid in understanding the operation and potential of the model *28* selective calling typing unit. The Baudot code contains five elements, each of which may assume a marking or spacing condition. This arrangement provides 32 distinct code combinations. All teletypewriters, however, are capable of performing approximately twice as many operations (printing or performing a function) as the number of available code combinations. This is accomplished by reserving two of the original code combinations to shift and unshift the platen (or type box in the case of the model *28*), placing the unit in the upper or lower case as desired.



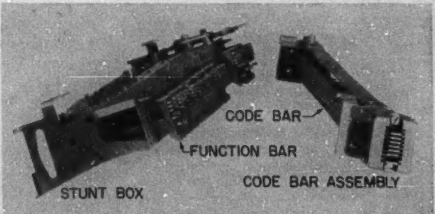


Fig. 3 (left). Rear view of the typing unit with the stunt box removed

Fig. 4 (above). Stunt box and code bar assembly showing relationship of function and code bars

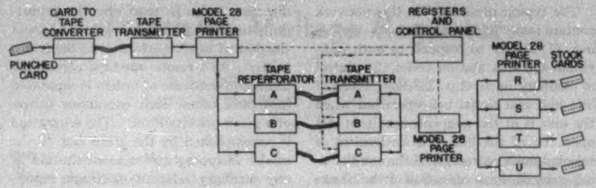

Fig. 5. Block diagram of integrated data processing system, utilizing model 28 equipment

The model *28* typing unit, when arranged for selective calling, is equipped with a device which activates or suppresses the printing mechanism. This arrangement permits an expanded use of the 32 code combinations of the Baudot code beyond that made available by the shift and unshift mechanism, since the unit can now be placed in a nonprint condition. In this condition the selector and stunt box are active, but the printing mechanism is suppressed; consequently, the same code combination that resulted in the printing of two different characters (one in the lower and one in the upper case) may be used to perform two additional functions, either electrical or mechanical, without the typing unit printing. These additional functions are prevented from occurring when the unit is in the print condition by positioning an auxiliary code bar to block all function bars arranged to perform special functions.

Suppression of the printing mechanism is accomplished by blocking the type box clutch. This blocking mechanism is controlled by elements in the stunt box which are set up to respond to a particular character or character sequence. Reception of this character or character sequence causes the blocking mechanism to unblock the type box clutch, placing the unit in the print condition. In this condition, the typing unit will operate as a normal teletypewriter. To return the unit to the nonprint condition a character sequence differing from that which placed the unit in the print condition causes the blocking mechanism to block the type box clutch. Code combinations selected for this latter sequence are preferably those which will result in no printing.

The versatility of the model *28* typing unit equipped with the blocking mechanism permits many variations of selective calling. The stunt box flexibility, as applied to selective calling, might best be illustrated by a brief description of two systems which are currently being placed in service.

BELL SYSTEM INSTALLATIONS

Teletype model *28* page printer equipment, now being placed in selective calling service by the Bell System, may be arranged to satisfy many diversified customer requirements. In their installations, each unit will shift to the print condition upon the reception of its preassigned character or sequence of characters, referred to as call directing characters (CDC). Units may be equipped to respond to more than one call directing character or character sequence so that a group of units, or all units, on a circuit may be placed in the print condition by the transmision of a single CDC. In addition, all units respond to two common codes, an end-of-address and an end-of-message code; the first shifts all units to a nonselect condition, and the second places the units in a nonprint and select condition.

As previously described, the position of the blocking mechanism determines whether the unit is in the print or nonprint condition. This mechanism is controlled by the call-directing and end-of-message codes. The units will be in the select or nonselect condition depending upon the position of an auxiliary (lockout) code bar. This code bar is controlled by elements in the stunt box which are set up to respond to the end-of-address and end-of-message codes. Reception of the end-of-address code causes the auxiliary code bar to be positioned to prevent selection of CDC function bars. Reception of the end of message code causes the auxiliary code bar to be positioned so as to allow selection of CDC function bars.

Any station desiring to communicate with one or more stations on the circuit may select them by transmitting his own and their assigned call directing characters. The end-of-address code sequence follows the transmission of the last CDC. All stations whether selected or not will have further selection suppressed, so that they will not respond to any selective calling codes except the end of message code. Call directing characters may, therefore, be used indiscriminately in the message without causing false selections. All stations not called will have printing suppressed and, therefore, will receive none of the communication. At the conclusion of the communication the end of message code sequence is transmitted, placing all units in the nonprint-select condition. In this condition, printing is suppressed and the stations are again capable of responding to call directing characters. The end-of-address code may be any character or character sequence. The end-of-message code, however, must be a sequence containing a minimum of two characters to insure that it will not appear in the body of the communication.

The number of stations possible in a network depends upon the character sequence used for call direction. If the 26 code combinations of the alphabet are used, a single call-directing character will provide 26 different station calls. If a 2-character sequence is employed, a total of 676 different sequences are possible. A 3-character sequence will provide 17,576 different call-directing sequences.

The selective calling stunt box arranged for Bell System Service also performs the following auxiliary functions: (1) The first character received by each unit, following the end-of-message code sequence, causes a busy lamp to light on all units on the circuit; this lamp will flash each time a space character is transmitted whether the unit has been selected or not. (2) The copy lights of each unit are turned on only when the unit is selected. (3) The keyboard lock mechanism of the units not selected is operated upon receipt of the end-of-address code to prevent inadvertent operation of the keyboard. (4) The line feed and signal bell operations are suppressed when the unit is not selected (nonprint condition).

Many optional features may be provided to meet particular customer requirements. These include the control of tape transmitters and reperforators at remote locations; motor control; the equipment of units to serve as spares in an installation containing many units, each having a different CDC; and the provision of a divide to shift the unit manually into the print condition when line monitoring is desired.

CAA INSTALLATION

The Civil Aeronautics Administration (CAA) is installing a nation-wide selective-calling flight-control network, utilizing the Teletype model *28* page printer set. This network consists of approximately 400 stations divided into 24 circuits. Each circuit contains from 10 to 30 stations, including relay stations for transmission to and from adjacent circuits. An expressway or trunk line is provided for transmission from coast to coast. The CAA installation and operating procedure differ from those of the Bell System. However, the model *28* page printer sets are essentially the same, differing primarily in the stunt box arrangements.

The CAA precedes the call directing characters with a 3-character code sequence that conditions the printer to respond to a station call. Upon receipt of the conditioning code a mechanism in the stunt box positions the auxiliary code bar (lockout code bar in the Bell System units) to allow the station call function bars to be selected. This code bar is held in the operated position for only the succeeding character. Consequently, if the first character of the station call does not follow the last character of the conditioning code the auxiliary code bar will return to its unoperated position, blocking the station call function bars associated with the blocking mechanism. The combination of the conditioning code and station code is a sequence of six characters which would not normally appear in the message. Use of the conditioning code permits the selection of any station at any time during a communiction without dropping out stations already selected.

Any station may communicate with one or more stations on the same circuit by transmitting the conditioning code and the desired station code. A selected unit is placed into the print condition upon receipt of the last character of the station code. An end-of-message sequence, similar to that employed in the Bell System installations, concludes the communication, placing all units in the nonprint condition.

To communicate with stations in adjacent areas requires the selection of a relay station in the circuit of the originating station. The relay stations contain reperforator-transmitter distributors controlled by model *28* page printer sets. Both of the units are placed into the circuit upon the receipt of the conditioning code and relay station code. The message is reproduced in the form of perforated tape by the reperforator portion of the reperforator-transmitter distributor. At the same instant, the circuit in the adjacent area is sampled to determine if it is busy. If the circuit is available, the tape is read by the transmitting portion of the reperforator-transmitter distributor and retransmitted. If the circuit is busy, the message is stored in the perforated tape for retransmission when the circuit becomes available.

The typing units used in this network contain many additional features, including: (1) ability to respond to both individual and area station codes, (2) control of auxiliary apparatus, (3) suppression of line feed and signal bell operation when the unit is in the nonprint condition, (4) operation of the line feed mechanism of selected units on receipt of the conditioning code, (5) local operation of the blocking mechanism for line monitoring, and (6) the ability of associated transmitter-distributor to shift the typing unit to the print condition without transmitting the conditioning or station codes.

Integrated Data Processing With Teletypewriters

Integrated data processing, as the name implies, is the integration data processes to achieve an automatic flow of information from one data processing machine to another. Mechanical and electronic data-processing devices of many types are available to perform the tedious tasks that are a part of office routines. Integration of this data-processing equipment may be simplified by the use of the Teletype model *28* page printer set in combination with perforated-tape-handling equipment. This simplification is possible because of the ability of the typing unit to perform many switching, sorting, and checking functions besides recording desired data.

An explanation of an order handling system providing rapid service on parts orders will illustrate the potential use of model *28* equipment in this field. This system accepts random orders for separation in accordance with priority levels, and then directs the items of each order to the proper stock area.

The input to the system, as shown in Fig. 5, is a punched card prepared by a key punch operator for each item on the order. The cards contain the necessary parts ordering information and the required directing codes which indicate the priority of the order and the item stock location.

The punched cards are placed into a card-to-tape converter which prepares a continuous common-language 5-unit (Baudot code) perforated tape. In addition to converting the information from card to tape, the converter inserts additional codes which are required for conditioning and releasing the switching equipment.

The prepared tape is placed into a transmitter of the type used for normal telegraph transmission. The information contained in the tape is transmitted to a model *28* page printer set. The order directing codes is "read" by the typing-unit stunt box mechanims which connect the desired tape reperforator to the transmitter. As a result, one tape containing a random sequence of orders is separated into three tapes, each containing orders of a given priority level. The separation is accomplished by the stunt box of the model *28* typing unit without the aid of any auxiliary relay or electronic equipment.

In addition to performing switching functions, the typing unit is available for recording the transmitted information. An invoice, shipping paper, or inventory record may, therefore, be prepared at the same instant and by the machine performing the circuit switching functions. Registers on a control panel are operated by contacts on the stunt box to provide a visible indication of the number of items, according to priority level and stock location, to be dispersed to stock areas.

The tapes prepared by the three reperforators *A*, *B*, and *C* are placed into their respective transmitters *A*, *B*, and *C* for transmission to the desired stock areas; the three tape transmitters operate one at a time under the control of a dispatcher. The stock area directing codes are "read" by a second model *28* typing unit which connects the desired stock area typing unit to the transmitter then operating. The stock area printer sets produce a stock ticket containing, in printed form, the same ordering information that appeared in the original punched cards. The typing unit performing this sorting operation operates registers to record the number and priority level of items dispersed to the stock areas.

The registers, operated by the two typing units performing the switching, provide the dispatcher with the load on each stock area, both in the number of items waiting for distribution and the number of items dispersed. Utilizing this information, the dispatcher is able to move the high priority orders first, but without overloading any particular stock area.

Conclusion

The experience in developing equipment for the systems described, together with the proved versatility and reliability of the stunt box, is expected to lead to an expanded use of the Teletype model *28* page printer set in selective calling, integrated data processing, and automation.

Transistor Voltage Regulator

R. H. SPENCER
ASSOCIATE MEMBER AIEE

T. S. GRAY
FELLOW AIEE

THIS paper describes a transistor voltage regulator circuit which takes advantage of the high voltage gain and low emitter resistance exhibited by the junction transistor. Emphasis is on a regulator circuit using a single transistor.

Circuit

The circuit of the basic transistor voltage regulator is illustrated in Fig. 1. Like other voltage regulators, this transistor regulator may be analyzed in terms of a 2-terminal-pair network as shown in Fig. 2.

The quantity to be regulated is the output voltage V_o which is a function of the two independent variables, the input voltage, V_{in} and the output current I_o, thus:

$$V_o=F(V_{in},I_o),$$

Variations of this output voltage, which are of concern here, may, when infinitesimal, be expressed in derivative form:

$$dV_o=\frac{\delta V_o}{\delta V_{in}}\,dV_{in}+\frac{\delta V_o}{\delta I_o}\,dI_o$$

For variations of noninfinitesimal size, the following expression is approximately correct provided the circuit is operated in the essentially linear region:

$$\Delta V_o=\frac{\delta V_o}{\delta V_{in}}\,\Delta V_{in}+\frac{\delta V_o}{\delta I_o}\,\Delta I_o$$

For this general regulator, the factor $\delta V_o/\delta V_{in}$ is called the stabilization factor F, and $-\delta V_o/\delta I_o$ is referred to as the output resistance, R_o. In terms of these definitions, the expression may be rewritten as follows:

$$\Delta V_o=F\Delta V_{in}-R_o\Delta I_o$$

The two factors F and R_o may be used to determine the actual stabilization for any output load resistance.

To determine the two describing parameters F and R_o for the transistor regulator circuit shown in Fig. 1, the incremental equivalent circuit of the regulator shown in Fig. 3 may be used.[1] Since F is $\Delta V_o/\Delta V_{in}$ when ΔI_o is made zero, the equivalent circuit for determination of F becomes that shown in Fig. 4. For this circuit $\Delta V_o/\Delta V_{in}$, and therefore F, is $r_b/(r_b+r_c)$.

To evaluate the output resistance R_o, which is $\Delta V_o/\Delta I_o$ when ΔV_{in} is made zero, the equivalent circuit of Fig. 5 is used. Loop equations for the voltages in this circuit are

$$0=\Delta I_c(r_c+r_b)+\Delta I_e(r_b+\alpha r_c)$$

$$\Delta V_o=\Delta I_c(r_b)+\Delta I_e(r_e+r_b)$$

and ΔI_e is thus:

$$\Delta I_e=\frac{\Delta V_o(r_c+r_b)}{(r_c+r_b)(r_e+r_b)-(r_b+\alpha r_c)(r_b)}$$

With the denominator rewritten the expression becomes:

$$\Delta I_e=\frac{\Delta V_o(r_c+r_b)}{r_c\left[r_e\left(1+\frac{r_b}{r_c}\right)+r_b(1-\alpha)\right]}$$

Since for most junction transistors $r_b/r_c<<1$, the output resistance is very nearly:

$$R_o=r_e+r_b(1-\alpha)$$

As the frequency of the output variation increases, the value of R_o increases until it reaches r_e+r_b at frequencies well above the alpha cutoff frequency.

For a representative transistor, the Raytheon *CK721*, the values of the parameters are

$r_c=700$ *K* ohms
$r_b=0.35$ *K* ohms
$r_e=0.020$ *K* ohms
$\alpha=0.975$

Using this transistor, one obtains for F, the stabilization factor:

$$F=\frac{r_b}{r_b+r_c}=\frac{0.35}{700}=\frac{1}{2{,}000}$$

The output resistance $R_o=r_e+r_b(1-\alpha)$ $=29$ ohms.

Thus, for low-voltage low-current loads, this circuit acts as an excellent regulator.

Voltage References

Silicon junction diodes now available serve as good voltage reference elements because in the so-called Zener breakdown region the voltage is relatively constant over a wide range of currents. Fig. 6 illustrates this Zener region as it appears in a representative silicon junction diode.

The voltage at which the so-called Zener breakdown occurs is fairly stable, exhibiting a temperature coefficient between −0.04 and +0.010 per degree centigrade.[2] Where smaller variations with temperature are required, the use of back-to-back Zener diodes allows an order of magnitude improvement in temperature coefficient.[2] This improvement occurs because the temperature coefficient in the Zener region can be made to have the opposite sign as that in the forward region, causing a first-order canceling of temperature coefficient.

The dynamic resistance of the Zener region is relatively low, ranging between 10 and 1,000 ohms. About 100 milliwatts of power can be dissipated in the Zener region by available junction diodes. Diodes of this type can be constructed with breakdown voltages ranging from a few volts to several hundred volts,[2] indeed a desirable feature of a voltage-reference unit.

In the transistor regulator shown in Fig 1, the reference element must pass a small fraction of the load current. Thus, the reference element must operate over a current range approximately $(1-\alpha)$ times the range of load currents. For the above 5-milliampere regulator, the biasing current of the reference must be at least 5(0.025) or 0.125 milliampere. In practice, the bias should be larger than this minimum value to avoid operation in the curved, low-current region of the Zener characteristic.

It should be noted that the incremental resistance of the reference element R_{ref} appears in the equivalent circuit as an increase in the base resistance of the transistor. This increase in equivalent base resistance will appear in the regulator output resistance as follows:

$$R_o=r_e+R_b(1-\alpha)$$

where

$$R_b=r_b+R_{ref}$$

Representative Circuits

Fig. 7 shows a practical voltage regulator circuit which takes into account the preceding principles. Modifications and extensions of this basic circuit are readily

made. Two transistors in cascade provide lower output resistance and better stabilization than the basic regulator. As shown in Fig. 8, this modification adds little to the complexity of the circuit.

The use of silicon junction transistors such as the type *901* of the Texas Instrument Company makes possible a higher output current than the use of similar germanium transistors, and permits operation to temperatures over 100 degrees centigrade. The use of the *n-p-n* transistors in this configuration results, of course, in a positive instead of a negative supply.

Experimental Results

The performance of an experimental voltage regulator is shown in Figs. 9 and 10. The measured values of stabilization factor and output resistance agree well with those calculated. In this regulator, a battery is used as reference. Figs. 11 and 12 indicate the characteristics of a regulator using silicon junction diodes as the reference element. It will be noticed that the stabilization factor of this regulator is not as good as that of the regulator with a battery reference. This inferior stabilization factor results largely from the fact that the diode Zener voltage changes with the unregulated voltage much the same as the voltage of a voltage regulator tube changes with the unregulated voltage in a regulated power supply using a voltage regulator tube as the reference.

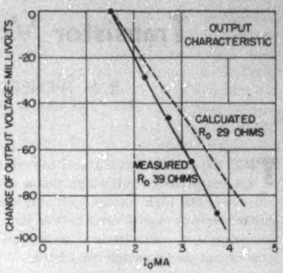

Fig. 10. Output characteristic for regulator using a battery reference

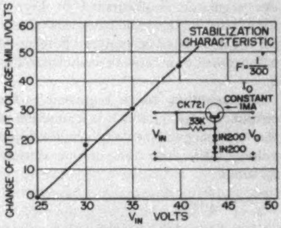

Fig. 11. Stabilization characteristic for regulator using a diode reference

Comparison With Vacuum-Tube Circuits

It is interesting to compare the transistor regulator and a vacuum-tube regulator which uses one tube. Only a pentode circuit can show as good a stabilization factor as does the transistor regulator. The pentode circuit suffers because the output resistance is $r_p/(\mu+1)$, which is seldom less than 200 ohms. Likewise, in a triode circuit, the output resistance is $r_p/(\mu+1)$, and the stabilization factor

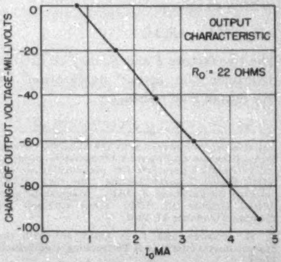

Fig. 12. Output characteristic for regulator using a diode reference

in a simple triode circuit is limited to $\mu/1$. Thus, the transistor circuit shows better inherent performance in these respects than single vacuum-tube circuits.

Conclusions

The simplicity of these circuits together with their good performance makes them well suited to regulate direct voltage within the limits of transistor capabilities.

A Comparison of Three Common Emitter Transistor Servo Preamplifiers

A. N. DeSAUTELS
ASSOCIATE MEMBER AIEE

Synopsis: Three multistage transistor servo preamplifiers representing transformer coupling, resistance-capacitance (R/C) coupling, and direct coupling respectively are compared on the basis of design problems and performance. Experimental data referring to temperature stability and voltage response supplement the design and performance calculations for a particular application. Primary advantages and disadvantages of each type are presented, together with a brief discussion of application generalities.

ONE OF the more popular configurations used for transistor amplifiers is that of the grounded or common emitter, whose vacuum-tube counterpart is the grounded cathode triode. There are three standard types of multistage common emitter amplifiers, and these are classified in accordance with the form of coupling used. These three types are transformer-coupled amplifiers, R/C-coupled amplifiers, and direct-coupled amplifiers. To provide information which may be used as a basis of approach by the engineer becoming acquainted with the transistor application field, these types are compared in this paper from the viewpoint of design problems and performance.

Nomenclature

α = short-circuit current amplification factor
I_c = d-c collector current
I_{c_0} = d-c collector current for zero emitter current
V_c = d-c collector voltage
E_{bb} = d-c supply voltage
R_L = d-c load resistance
S = stability factor
e_{in} = a-c transistor input voltage
e_T = a-c transistor output voltage
G = power gain
r_b = equivalent transistor base resistance
r_c = equivalent transistor collector resistance
r_e = equivalent transistor emitter resistance
r_{in} = a-c transistor input impedance
r_0 = a-c transistor output impedance
r_L = a-c transistor load impedance
θ = voltage phase shift

Design Considerations

Preliminary Design Facts

Each amplifier covered consists of three stages of amplification using *PNP* alloy junction germanium transistors. The transistors in the first two stages were 50-milliwatt types with α approximately equal to 0.97. A Minneapolis-Honeywell *P6* 2-watt transistor was used in the third stage. The α and I_{c_0} values used in design calculations were selected from the manufacturer's data and test and test data as representative for the transistor types. The same load was used as the foundation of design for each type. Although a particular case is cited in this paper, the design principles and general comparison should, with few exceptions, hold true in most applications for which a choice of the three amplifier types can be made. Possible applications for amplifiers of the types considered could include use as a preamplifier driving a power transistor, vacuum tube, or magnetic amplifier output stage.

Performance is evaluated for one condition of load and source impedance. The load is a 50-ohm resistor coupled by a transformer presenting approximately a 4-kilohm impedance to the amplifier. Source impedance is about 10 ohms. Typical operating points were arbitrarily selected. In the experimental study, the same transistors were used in all three amplifiers. Calculations are based on a signal frequency of 400 cycles.

Design problems connected with certain applications may limit or dictate the type of coupling used. This study is based on the premise that any type of coupling is possible for the application being considered.

Transformer-Coupled Amplifier

Fig. 1 presents a 3-stage transformer-coupled amplifier. The interstate transformers used in transistor circuitry perform more efficiently at lower values of primary direct current. In addition, the d-c collector-to-emitter potential must be high enough to forestall clipping at higher signal levels. With these two points in mind, the first and second stages were designed for d-c operating points of V_c = 10 volts, I_c = 0.3 milliampere (ma) for a power supply of 28 volts. The third-stage operating point was arbitrarily selected as typical for the *P6* power transistor. Design of the d-c bias networks[1] was based on a stability factor S of 1.3. This stability factor is defined as the partial derivative of collector current I_c, with respect to zero emitter collector current I_{c_0}, or $S = dI_c/dI_{c_0}$.

Stage-by-stage design calculations are presented in the Appendix. The emitter capacitor serves as an a-c by-pass to reduce degeneration across the emitter d-c bias resistor.

R/C-Coupled Amplifier

A 3-stage R/C-coupled amplifier is shown in Fig. 2. Design of this circuit is straightforward. Since the need for lower values of collector current is not of as great concern with R/C-coupling, d-c operating points of V_c = 6 volts and I_c = 1 ma were selected for the first and second stages. If a typical operating point was assigned to the third stage however, a situation detrimental to per-

Paper 56-37, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 18, 1955; made available for printing November 16, 1955.

A. N. DeSautels is with the Minneapolis-Honeywell Regulator Company, Minneapolis, Minn.

formance would result when bias stabilization resistance values were calculated. The low value of the base bias resistors would have a shunting effect on the input to the third stage. This effect can be countered in two ways. One way would be to increase the power supply voltage for a given operating point. This would result in larger values for the bias resistances with a corresponding reduction in shunt effect and a related decrease in coupling network losses. An alternate way would be to select an operating point that would permit higher values of d-c bias resistance for a given power supply. Fig. 2 illustrates the second method. A stability factor *S* of 1.3 was used in the design of the d-c bias networks. The emitter by-pass capacitors should be as high as possible to minimize degeneration.

DIRECT-COUPLED AMPLIFIER

The interrelation of stages of the direct-coupled amplifier make necessary a special design approach. Fig. 3 presents a direct-coupled amplifier circuit designed for stability of performance with temperature variations. Stability can be obtained by fixing the base bias voltages and keeping the emitter current essentially constant. To accomplish this, it is desirable that the emitter circuit resistances be in the order of ten times greater than the collector circuit d-c resistances. In order words, $R_3 >> R_1$ and $R_4 >> R_2$.

The collector-to-ground direct voltage of one stage is the base bias voltage of the following stage. This value is approximately the same as the emitter voltage of that stage. These conditions introduce special problems where operating points and power supply voltage are concerned.

To maintain practical values of collector-to-emitter d-c voltage in the 3-stage amplifier treated here, the d-c power supply must be considerably greater than the 28-volt supply used with the transformer- and R/C-coupled amplifiers. Operation of a bias stabilized 3-stage direct-coupled amplifier with the emitter and collector circuit resistance relationships previously mentioned and with a 28-volt d-c supply would be inconceivable even at the low operating points utilized for the circuit of Fig. 3. For good bias stabilization, it is preferred that $R_3 >> R_1$ and $R_4 >> R_2$ by a factor of about 10. For the first stage, this means that the voltage across R_3 will be approximately ten times the voltage across R_1. At a d-c operating point of 2 volts, 1 ma, the voltage from *A* to ground using a 28-volt supply would be approximately 2.5 volts direct current, which would also be the approximate voltage from *B* to ground. Thus, from *B* to ground, 2.5 volts would be available to be dropped across T_2 and R_2. Obviously, this becomes impossible at the operating points shown and use of operating voltages lower than those shown would approach impracticality, particularly in the third stage.

At $E_{bb}=100$ volts, it is possible to increase the operating voltages at the expense of some bias stabilization efficiency. Of course, bias stabilization effectiveness could be maintained at higher operating voltages than those shown by increasing the value of E_{bb}. D-c analysis of Fig. 3 reveals that the voltage from *A* to ground is 10 volts direct current, which is essentially the voltage from *B* to ground. $V_{c2}=3$ volts direct current, which leaves the voltage from *C* to ground and therefore *D* to ground approximately equal to 7 volts direct current. This permits sufficient voltage for the $V_{c3}=6$-volt drop and the direct voltage drop across the transformer primary.

Performance

POWER GAIN

Because of the bilateral nature of the transistor (e.g., input impedance is a function of the load and output impedance is a function of the source), it is necessary that calculation of performance of a transistor amplifier be started from the last stage. Input impedance and power gains are calculated, and the input impedance combined with the coupling network becomes the load impedance for the preceding stage. The mechanics of performance calculations

for the amplifiers treated in this paper are presented in the Appendix.

Table I presents the comparative theoretical and experimental power gains for all three amplifiers. The coupling network losses add up to 3 decibels (db) for the R/C-coupled amplifier and about 1 db for the direct-coupled circuit. Increasing E_{bb} to 100 volts for the R/C-coupled network for the same operating points with related changes in the d-c bias resistances would reduce coupling network losses to 1 db with a resultant total calculated power gain for the specified load of about 83.5 db.

The transistor parameter values used in the calculations were obtained from average-characteristics curves for the operating points concerned and are necessarily approximate. The difference between calculated and experimental values could be accounted for by differences between approximate and actual parameter values of the transistors used.

It can be noted that changing the power supply voltage for the direct-coupled amplifier would have no effect on power gain if operating points are kept constant by varying the appropriate emitter circuit resistances. No change would be required in base bias resistance values.

Repeatability of power gain with transistor replacement was observed during interchanging, in the first two amplifier stages, ten transistors representing three manufacturers. About a 10-per-cent spread between highest and lowest values was noted for the over-all power gain. Feedback networks could be used to decrease this spread at the expense of some over-all power gain.

Input and Output Impedances

Table II presents a comparison of input and output impedances. Calculation processes are based on approximate parameter values for respective operating points and are detailed in the Appendix. The explanation for the comparatively high experimental input impedance may be that actual transistor parameters, particularly r_e and α are higher than those approximated for the calculations.

It would be well to emphasize at this point that, due to the probability expressed in the preceding statement, any comparison between theoretical and experimental data should be from a qualitative viewpoint.

Temperature Stability

Fig. 4(A) presents, for the three amplifiers under study, the comparison of power gain as a function of temperature increase. The stability of the R/C-coupled and direct-coupled amplifiers appears superior to that of the transformer-coupled amplifier. An increase in temperature has the effect of introducing changes in transistor parameters and direct current. Although these changes are minimized with bias stabilization, they still exist. For the transformers used in the transformer-coupled amplifier, small increases in the d-c levels will cause comparatively large decreases in the transformer shunt impedances. This means increased shunt impedance losses with an associated decrease in power transfer from transistor to load. Since a mismatch already exists between stages in R/C and direct coupling, the effect of small changes in transistor parameters is not as pronounced with these types of coupling.

	1 ST STAGE	2 ND STAGE	3 RD STAGE

* r_L = output load on amplifier.

Fig. 4(B) shows power gain as a function of temperature decrease. Under these conditions, the capacitors in the circuit become a limiting factor. The characteristics of the capacitors are such that effective capacitive reactance and series resistance values increase with temperature decrease. Where the emitter by-pass capacitors are concerned this results in increased degeneration in the emitter circuits with a resultant gain decrease for R/C- and direct-coupled circuits. In the transformer-coupled amplifier, with the exception of the first stage, the emitter by-pass capacitors are entirely in the collector circuits. These capacitors present reactance values which are small in comparison to the load and shunt impedances. Therefore the increased capacitive reactance and series resistance with decreased temperature, in the case of the second and third stages, has little or no gain reduction effect. Where the base circuit-blocking capacitors are concerned, the increasing reactance and resistance increases the load impedance on the preceding stages sufficiently to increase power transfer and to compensate for the increased reactance losses. In short, there is a reduction in first-stage gain because of increasing degeneration; a constant or slightly increasing second-stage gain; and a slightly increasing third-stage gain. A contribution to third-stage gain could be made by increasing shunt impedance of the output transformer. At the d-c levels used, a temperature decrease could decrease the collector current sufficiently to cause changes in output transformer parameters. However any changes in the d-c levels of the interstage transformers would be negligible.

PHASE SHIFT AND FREQUENCY RESPONSE

Calculated voltage phase shift is presented in Table III. Methods of calculation may be found in the Appendix. The apparently large phase shifts for the R/C- and direct-coupled amplifiers are due primarily to the effect of the heavily inductive load. Use of a resistive or capacitive load would materially decrease the effective voltage phase shift.

Fig. 5 presents the frequency response curves for the three amplifiers. It should be remembered in comparing the curves that each amplifier is operating at different operating points. The sharp increase in gain of the transformer-coupled amplifier could be attributed to the increasing transformer inductive reactance and decreasing capacitive reactance of the emitter by-pass capacitor. Increasing inductive reactance permits greater power transfer to the respective loads for each stage, while decreasing capacitive reactance decreases degenerative losses. The tapering-off at higher frequencies could conceivably be due to increasing transformer core losses. At 400 cycles, hysteresis and eddy current losses have been considered negligible, but at higher frequencies these losses may acquire importance. Eddy current losses are proportional to the frequency squared while hysteresis losses are approximately directly proportional to frequency. Thus at 20,000 cycles, eddy current losses are approximately 2,500 times greater than at 400 cycles while hysteresis losses are about 50 times greater.

In the R/C- and direct-coupled amplifiers, the gain increase and taparing off effects are less pronounced, since only one transformer is involved. The differences between the points at which the tapering-off trend occurs is attributable to the operating points of the amplifiers. At the operating point of the third stage of the direct-coupled amplier, the inductance of the load transformer is higher

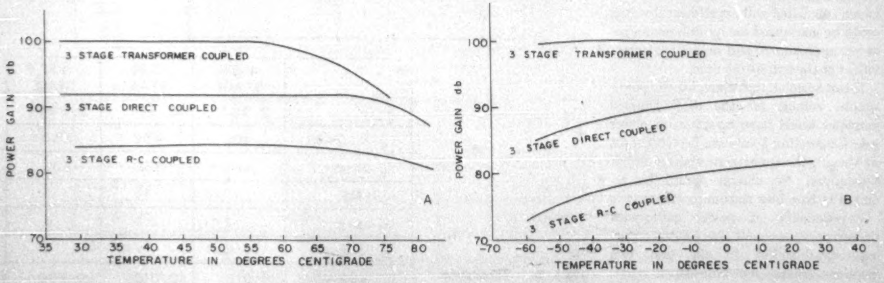

Fig. 4. Variation of power gain with temperature

Table III. Voltage Phase Shift

Type of Amplifier	Calculated Voltage Phase Shift
Transformer-coupled	−157°
R/C-coupled	− 64°
Direct-coupled	− 78°

than at the operating point of the third stage of the R/C-coupled amplifier. Thus, peak gain or maximum transfer condition is approached sooner with the direct coupled amplifier than with the R/C-coupled amplifier. Operation at the same operating points should give quantitatively similar curves.

Number of Components

A quantitive comparison of the components included with each type of amplifier is presented in Table IV. The number of components required for the direct-coupled amplifier is appreciably less than is required by each of the other two amplifiers. No attempt is made to compare production costs of the amplifiers; but, from a strictly general viewpoint, it is apparent from Table IV that cost of components for the direct-coupled amplifier will run considerably less than for the other two types.

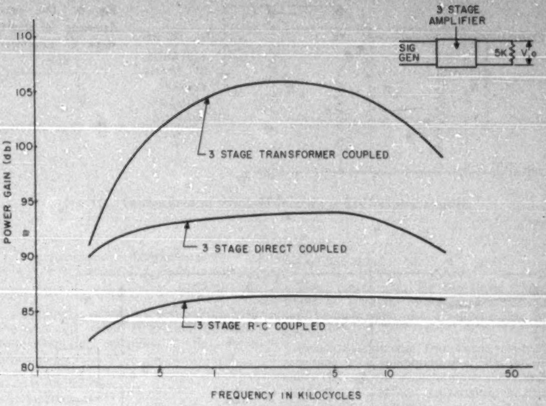

Fig. 5. Frequency response curves

Discussion

In reference to the d-c operating points of the third stages, the possible alternating voltage swing is limited by the d-c collector to emitter voltage. By keeping this voltage at a sufficiently high value, the amplifier is enabled to handle larger input signal levels without clipping. While this is relatively easy to accomplish with R/C and transformer coupling, the problems connected with direct coupling make this possible only by increasing power supply voltage or reducing bias stabilization network resistances. The lower the collector voltage operating point, the lower will be the possible sine wave voltage across the load.

Increase in phase shift with temperature increase should be experienced by all three amplifiers, and will occur almost entirely through the transformers in the circuits. Increased temperatures will change the d-c operating level of the transistors. This change will cause variations in transistor output impedance, transistor input impedance, and transformer primary inductance in such a manner as to increase phase shift through the transformer. This shift should be most pronounced with transformer coupling where three transformers are involved.

The characteristics of the capacitors at increased temperatures are such that little phase shift as a result of capacitance change will be evident. With decreased temperatures, however, capacitance suffers a considerable decrease, producing a phase shift effect that counters, to a certain extent, phase shift changes which may occur through the transformers. Thus, phase shift variations should be less pronounced with decreasing temperature than with increasing temperatures.

Where R/C and direct coupling are concerned the low temperature characteristics of the capacitors adversely affect the low-temperature performance of the amplifiers. Capacitors with improved temperature characteristics would substantially improve the low-temperature performance of R/C- and direct-coupled circuits.

Transformer coupling has the advantages of high-gain and excellent low-temperature performance. Disadvantages include high-temperature performance and phase shift problems which could be alleviated to a certain extent by using transformers rated for higher levels of primary direct current.

Direct coupling has the fewest components and provides good high-temperature performance, little phase shift, and a substantial power gain. Its chief disadvantage in so far as the amplifier treated in this paper is concerned, appears to be the necessity for increasing the power supply voltage in order to maintain the desired bias stabilization network without reducing transistor d-c operating levels below a practical value. However, it is conceivable that a more complete investigation of direct-coupled circuitry could produce a temperature-stable amplifier operating from a 28-volt d-c supply.

The R/C-coupled amplifier could, in most instances, be rated almost on a par with the direct-coupled amplifier. Both R/C and direct coupling display gain deterioration with decreased temperature. This effect is due primarily to the low-temperature characteristics of the tantalytic emitter by-pass capacitors used in the circuits.

General Considerations

This paper has discussed three circuits on the basis of a 10-ohm source impedance, a specified 4-kilohm load impedance and a frequency of 400 cycles. However, different application requirements necessitate additional design considerations.

At frequencies lower than 400 cycles, the value of by-pass and coupling capacitor should be increased to minimize phase shift and degenerative losses. At higher frequencies, it would be primarily from economy and size standpoints that the capacitance values need be decreased. In the transformer-coupled amplifier,

Table IV. Number of Components

Type of Amplifier	Transformers	Capacitors	Resistors	Transistors
Transformer-coupled	3	5	9	3
R/C-coupled	1	5	11	3
Direct-coupled	1	3	7	3

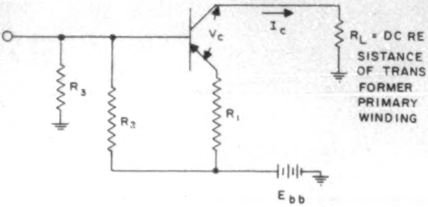

Fig. 6. D-c configuration for single stage of amplification

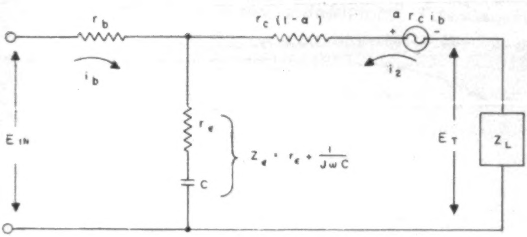

Fig. 7. Equivalent circuit for common emitter amplifier stage

lower or higher frequences, as shown in Fig. 5, could so affect transformer characteristics that different transformers would be required.

For those applications with higher impedances, input impedance in the common emitter configuration may be increased, at the expense of some power gain, by the use of degenerative feedback. For the amplifiers considered in this paper, an unbypassed resistance R placed in the emitter circuit would increase the input impedance by approximately $\alpha/1-\alpha$ times R for $r_L << r_c\,(1-\alpha)$. R would ordinarily be much smaller than the emitter bias resistance, and should therefore cause no noticeable change in the operating point. High values of input impedance with appreciable power gain can be obtained by this, method, especially when a high α-transistor is used. However, the actual input impedance seen by the source would be limited by the values of the base bias resistances.

This limitation could be removed by transformer coupling to the source, since with transformer coupling the base bias resistances do not shunt the transistor input. It may be practical in some instances to use the high input impedance characteristics of a common collector configuration in the first stage with transformer or R/C-coupling to the following common emitter stages.

Load impedances different from the one specified would require recalculation of d-c bias values and a-c performance with the respective d-c and a-c values of the load impedance in the appropriate design and performance equations presented in the Appendix.

Degenerative feedback with the unbypassed emitter circuit resistance could also be used to satisfy lower gain requirements. For example, the second stage of the transformer coupled amplifier of Fig. 1 was calculated to have a power gain of about 32.6 db for the chosen operating point. A power gain of 20 db for this stage would require, from equation 7, an emitter resistance, r^e, of about 1,500 ohms. Since the internal emitter resistance for this stage was held to be about 50 ohms, an external un-by-passed emitter resistance of 1,450 ohms would be needed to obtain the desired gain. The second-stage input impedance would increase, in this case, from the originally calculated 2,390 ohms to about 42 kilohms. This would increase the load impedance for the preceding stage with a resulting increase of the power gain of that stage of less than 1 db. Thus, the over-all power gain of the 3-stage transformer-coupled amplifier is reduced from the original 102.1 db to about 90 db. This principle is also applicable to the R/C- and direct-coupled amplifiers.

Appendix

Design and Performance Calculations

THREE-STAGE TRANSFORMER-COUPLED AMPLIFIER

To assist the engineer newly indoctrinated in transistor applications, the principles and processes associated with the design and performance calculations are demonstrated stage by stage. Bias stabilization resistance values are obtained through application of equations for a single battery supply.[1] The d-c configuration for each stage can be represented by the circuit of Fig. 6. For the first stage

$$R_1 = \frac{\alpha(E_{bc} - V_c - R_L I_c)}{I_c - I_{c0}} \qquad (1)$$

where

$\alpha = 0.967$, arbitrarily selected as representative
$E_{bb} = 28$ volts, d-c power supply
$V_c = 10$ volts direct current
$R_L = 1$ kilohm
$I_c = 0.3$ ma direct current
$I_{c0} = 10\ \mu a$ direct current
$R_1 = 58.7$ kilohms

$$R_2 = \frac{S-1}{\frac{1-S+\alpha S}{R_1} - \frac{I_c - SI_{c0}}{E_{bb}}} \qquad (2)$$

where

$S = 1.3$, arbitrarily selected
$R_2 = 50$ kilohms

$$R_3 = \frac{E_{bb}(S-1)}{I_c - SI_{c0}} \qquad (3)$$

$R_3 = 29.2$ kilohms

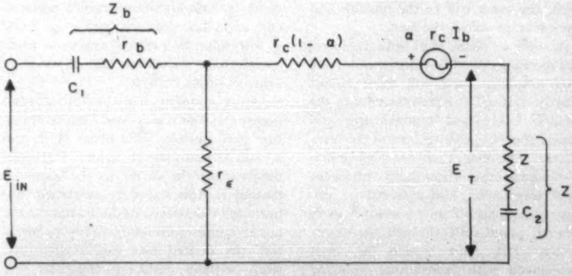

Fig. 8. Equivalent circuit for intermediate stage of transformer-amplifier

Table V. Transformer Parameter Data

Units	Transformer 1	Transformer 2	Transformer 3
R_g kilohms	100	100	17
R_L ohms	2,400−j40	300−j40	50
R_p ohms	1,000	1,000	300
R_s ohms	200	100	10
a^2 ohms	20	20	100
ωL ohms	25,100	20,100	5,000

Since the d-c operating conditions of the first and second stages are the same, the stabilization network resistances will be the same for both stages.

In the third stage, however

$\alpha=0.925$
$V_c=25$ volts
$I_e=5$ ma
$I_{co}=0.3$ ma
$R_L=250$ ohms
$S=1.3$
$E_{bb}=28$ volts

Applying these values to equations 1, 2, and 3

$R_1=345$ ohms
$R_2=122$ ohms
$R_3=1.82$ kilohms

Performance calculations are based on approximate transistor parameter values obtained from average characteristic curves for the operating points concerned. Fig. 1 includes parameter values assumed for the transformer coupled amplifier. Applying the equation for maximum performance[3] to each stage establishes for the third stage a load impedance for maximum gain

$$r_{\max}=r_c(1-\alpha)\sqrt{\frac{r_b(1-\alpha)+r_e}{(r_e+r_b)(1-\alpha)}}=16.5\text{ kilohms} \quad (4)$$

The input impedance corresponding to r_L maximum

$$r_{\text{in}}=\sqrt{(r_e+r_b)\left(r_b+\frac{r_e}{1-\alpha}\right)}=281\text{ ohms} \quad (5)$$

Maximum third stage gain for the specified conditions

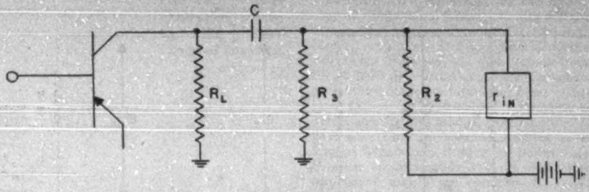

Fig. 10. Configuration of interstage coupling in R/C-coupled amplifier

$$G_{\max}=\frac{\alpha^2 r_c}{[\sqrt{r_e+r_b(1-\alpha)}+\sqrt{(r_e+r_b)(1-\alpha)}]^2}\cong 33\text{ db} \quad (6)$$

Maximum performance figures for both the first and second stages will be same. Application of equations 4 through 6 produces for each of the first two stages

$r_{L\max}=100$ kilohms
$r_{\text{in}}=1{,}620$ ohms
$G_{\max}=39.2$ db

Total maximum power gain of the three stages for peak conditions would be 111.4 db. With the selected load of a 4-kilohm impedance, third-stage gain would be

$$G=\frac{\alpha^2 r_c{}^2 r_L}{[r_c(1-\alpha)+r_L]\times[r_c r_e+r_c r_b(1-\alpha)+r_L(r_e+r_b)]} \quad (7)$$

$G_3\cong 31$ db and

$$r_{\text{in}}=r_b+r_e\left[\frac{r_c+r_L}{r_c(1-\alpha)+r_L}\right] r_{\text{in}_3}\cong 300\text{ ohms} \quad (8)$$

With a 20-to-1 transformer impedance ratio, the third stage r_{in} appears as a r_L of 6 kilohms for the second stage. Applying equations 7 and 8 results in

$G_2\cong 32.6$ db and
$r_{\text{in}_2}=2{,}390$ ohms

The transformer impedance ratio of 20 to 1 makes r_{in_2} appear as a r_L of 43 kilohms to the first stage. Applying equations 7 and 8 results in

$G_1=38.5$ db
$r_{\text{in}_1}=1{,}935$ ohms

Total power gain for the three stages would be 102.1 db representing a voltage gain of 18.8 (10^3) and a current gain of 830 (10^3).

Phase shift in the transformer-coupled amplifier is a combination of the phase shifts through the transformers and phase shifts introduced by capacitance in the emitter and base circuits and the inductive loads of each stage. Fig. 7 presents the equivalent circuit for the first stage.

Analysis by Kirchhoff equations produces the relationship

$$\frac{e_T}{e_{\text{in}}}=\frac{-\alpha r_c Z_L}{r_b(r_c-\alpha r_c+Z_L)+Z_e(Z_L+r_c)} \quad (9)$$

where Z_L = impedance presented by the reactive load, and Z_e consists of emitter resistance and reactance of the emitter circuit by-pass capacitor. For the first stage, Z_L at $400=1{,}000+j25{,}100$ and $Z_e=50-j40$. Applying parameter values from Fig. 1 to equation 9

$$\frac{e_T}{e_{\text{in}}}=-(278\underline{/106^\circ})$$

For the second and third stages, the equivalent circuit becomes that of Fig. 8, where C_1 is the blocking capacitor in the base circuit and C_2 is the emitter bias resistance by-pass capacitor.

Equation 9 is still applicable with $Z_e=V_e$ and Z_L including the capacitive reactance of C_2. Ordinarily this reactance will be so small as to be negligible in comparison to the inductive reactance of the load. The value r_b shall in this instance include the reactance of C_1. The reactance of C_1 in general is small in comparison to other circuit impedances. For the second stage $Z_L=1{,}000+j20{,}100$, $Z_e=50$, and $r_b=1{,}000-j40$. From equation 9

$$\frac{e_T}{e_{\text{in}}}=-(230\underline{/81^\circ})$$

For the third stage, $Z_L\cong 300+j5{,}000$, $Z_e=5$, and $r_b\cong 250-j40$. Applying equation 9

$$\frac{e_T}{e_{\text{in}}}=-(184\underline{/79.1^\circ})$$

to obtain the voltage phase shift through the transformers applying the equation[1]

$$\theta=\tan^{-1}\frac{(R_g+R_p)(R_{\text{in}}+R_s)a^2}{\omega_L[R_g+R_p+(R_{\text{in}}+R_s a^2)]} \quad (10)$$

where

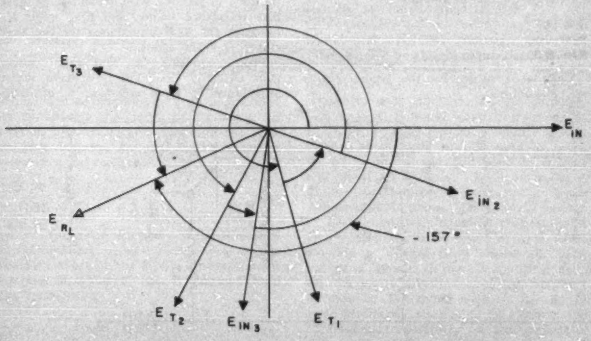

Fig. 9. Voltage phase shift phasors for the transformer-coupled amplifier

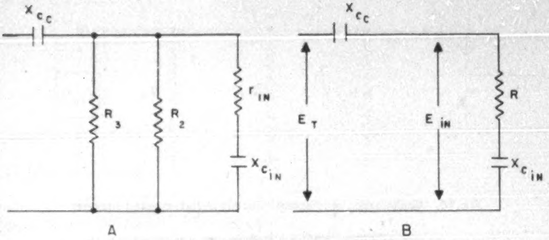

Fig. 11. Simplification of coupling network

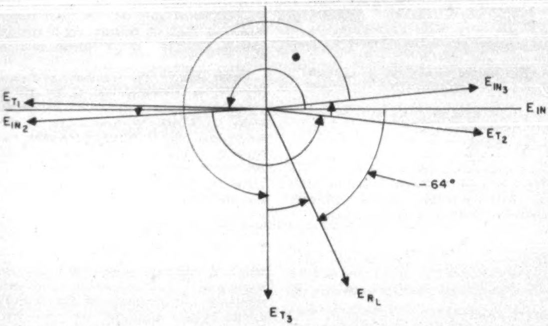

Fig. 12. Voltage phase shift phasors for the R/C-coupled amplifier

R_g = output impedance of preceding stage in ohms
R_{in} = input impedance of following stage in ohms
R_p = primary winding resistance in ohms
R_s = secondary winding resistance in ohms
a = turns ratio
L = primary inductance in henrys
$\omega = 2\pi \times$frequency in cycles per second

Table V presents parameter data for each transformer in the amplifier. R_L includes the effect of the base circuit-blocking capacitors. Solving equation 10 for all three amplifiers

$\theta_{T_1} = 54°$
$\theta_{T_2} = 21°$
$\theta_{T_3} = 42°$

Combining the angles phasorially as in Fig. 9 provides a resultant voltage phase shift for the 3-stage transformer-coupled amplifier of −157 degrees.

THREE-STAGE R/C-COUPLED AMPLIFIER

The same procedure as was used with transformer coupling is used to calculate bias stabilization resistances for the R/C-coupled amplifier. Fig. 7 is again a representation of the d-c configuration for each stage with R_L in this case being the resistor in the collector circuit.

Applying equations 1 through 3 to each stage using related values from Fig. 2 gives, for the first stage, in kilohms:

$R_1 = 11.7$
$R_2 = 6.5$
$R_3 = 8.5$

Calculated values for the second stage are, in kilohms:

$R_1 = 17.5$
$R_2 = 15.5$
$R_3 = 8.5$

and for the third stage, in ohms:

$R_1 = 1{,}750$
$R_2 = 780$
$R_3 = 2{,}300$

Analysis of the performance of the R/C-coupled amplifier involves performance calculations for each stage and correction for stabilization network attenuation. The maximum available gain possible with a 3-stage R/C-coupled amplifier can be found from the relationship

$$G_{max} = \frac{\alpha_1^2\alpha_3^2 r_{c_3}}{4(1-\alpha_1)[r_{e_1}+r_{b_1}(1-\alpha_1)](1-\alpha_3)} \times \left(\frac{\alpha_2}{1-\alpha_2}\right)^2 \qquad (11)$$

where subscripts refer to the stage concerned. Substituting values from Fig. 2 obtains

$G_{max} \cong 87$ db

Load impedance for maximum third stage performance is

$$r_L = r_c(1-\alpha) \qquad (12)$$

$$= 22.5 \text{ kilohms}$$

Third-stage power gain for this load is, from equation 7, 34.8 db. For the selected load of a 4-kilohm impedance, third-stage power gain becomes approximately 31.6 db, with input impedance from equation 8≅307 ohms. This impedance in parallel with the shunt resistances as shown in Fig. 10 becomes the load for the preceding stage. From third-stage bias network values previously calculated and second-stage R_L from Fig. 1, second-stage load impedance becomes

$$r_{L_2} = \frac{1}{\frac{1}{R_L}+\frac{1}{R_3}+\frac{1}{R_2}+\frac{1}{\frac{1}{R_{in_3}}}} \cong 200 \text{ ohms}$$

From equation 7, second-stage power gain $G_2 \cong 22.2$ db, and from equation 8, second-stage input impedance becomes approximately 900 ohms. This input impedance in parallel with second-stage base bias resistance values and first stage R_L becomes the load impedance for the first stage, $r_{L_1} \cong 725$ ohms.

From equation 7, first-stage power gain $G_1 \cong 27.7$ db. The first-stage input impedance is, from equation 8, approxi-

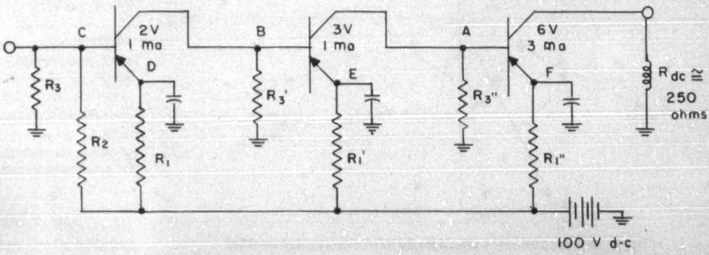

Fig. 13. Direct-coupled circuit used as basis for calculations

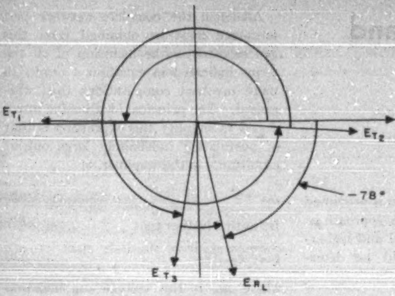

Fig. 14. Voltage phase shift phasors for the direct-coupled amplifier

mately 880 ohms, but the shunting effect of the base bias resistances results in the presentation to the signal source of an impedance, $r_{in_1}\cong 710$ ohms.

Total power gain for the three stages becomes the sum of the corrected power gains for each stage, and for a 22.5-kilohm load, is 84.7 db, while for the selected 4-kilohm load it is 81.5 db.

Phase shift in the R/C-coupled amplifier is a combination of phase shifts introduced by capacitance in the emitter circuits, reactance in the coupling networks, and the reactive loads of each stage. The equation 9 applies equally well to the R/C-coupled amplifier. For the first stage $Z_e=24-j4$ and $Z_L=792-j107$. Z_L includes the reactive effect of emitter circuit by-pass capacitance on input impedance. Using equation 9 and values from Fig. 2, produces for the first stage

$$\frac{\Sigma T_1}{\Sigma_{in_1}}=-(22.4\underline{/-1^\circ})$$

For the second stage $Z_\Sigma=20-j4$ and $ZL=197-j55.5$

$$\frac{\Sigma T_2}{\Sigma_{in_2}}=-(5.6\underline{/-8.2^\circ})$$

For the third stage $Z\Sigma=5-jr$ and $Z_L=250+j6{,}260$

$$\frac{\Sigma T_3}{\Sigma_{in_3}}=-(246\ \underline{/85^\circ})$$

Phase shift in the transformer coupling to the load is from equation 10 equal to 26 degrees, obtained using a primary inductance value of 2.5 henrys related to the 4-ma third-stage d-c operating level. Voltage phase shift relationship through the capacitive coupling network is obtained by simplifying the circuit of Fig. 11(A) to that of Fig. 11(B) and obtaining the relationship between Σ_T and Σ_{in} in terms of resistance and reactance. Thus,

$$\frac{\Sigma_{in}}{\Sigma_T}=\frac{R-jX_{c_{in}}}{R-j(X_{c_{in}}+X_{c_c})} \qquad (13)$$

where X_{c_c} is the reactance of the 10-microfarad coupling capacitor and $X_{c_{in}}$ is the reactive effect of the 20 *μfd* emitter circuit by-pass capacitance. Z_{in} is obtained from the relationship

$$Z_{in}=r_b+\frac{1}{1-\alpha}\left(r_e+\frac{1}{j\omega c_{in}}\right) \qquad (14)$$

and

$$R-jX_{c_{in}}=\frac{1}{\frac{1}{Z_{in}}+\frac{1}{R_2}+\frac{1}{R_3}} \qquad (15)$$

Applying equations 14, 15, and 13 to the coupling between the first and second stages produces the relationship

$$\frac{\Sigma_{in_2}}{\Sigma_{T_1}}=0.992\ \underline{/2.9^\circ}$$

and repeating the procedure for the coupling between the second and third stages produces

$$\frac{\Sigma_{in_3}}{\Sigma_{T_2}}=0.963\underline{/11^\circ}$$

Combining all angles phasorially as in Fig. 12 provides a resultant voltage phase shift for the 3-stage R/C-coupled amplifier of −64 degrees.

THREE-STAGE DIRECT-COUPLED AMPLIFIER

Bias resistances are approximated on the basis of desired transistor d-c operating points and power supply voltage. Fig. 13 shows that calculations are started from the third stage. With 3 ma in the collector circuit, a 0.75-volt drop will occur across the 250-ohm d-c resistance of the transformer primary. With a 6-volt drop across the transistor, 93.25 volts would remain to be dropped across R_1''. At approximately a 3-ma emitter current, this would make $R_1''\cong 31$ kilohms. With the voltage at *A* almost equivalent to the voltage at *F*, essentially 7 volts must be dropped across R_2''. With a 1-ma second-stage collector current, $R_2''\cong 7$ kilohms. Ten volts at *E* would leave 90 volts across R_1'. At 1 ma, $R_1=90$ kilohms. With voltage at *B* essentially the same as at *E*, R_2 for 1-ma first-stage collector current will equal 10 kilohms. With 12 volts at *D*, R_1 must handle 88 volts and at 1 ma will equal 88 kilohms. To maintain voltage at *C* approximately equal to that at point *D*, ratio of R_2 to R_3 must be such as to provide a 12-volt drop across R_3. The values of R_2 and R_3 have a shunting effect on the input impedance of the amplifier as seen by the signal source. R_2 and R_3 were arbitrarily selected as 88 kilohms and 12 kilohms respectively for the purpose of this application.

Performance calculations for the direct-coupled amplifier follow, to a certain extent, the pattern of those for the R/C coupled amplifier. The maximum available gain, from equation 11, with values from Fig. 3 $\cong$89 db. Load impedance for maximum third-stage performance, from equation 12, is 18.75 kilohms. Third-stage power gain for this load is, from equation 7, 34.8 db. For the selected load of a 4-kilohm impedance, third-stage power gain becomes approximately 31.7 db with input impedance and, from equation 8, $\cong$250 ohms. This impedance in parallel with the base bias resistance becomes the load for the preceding stage. With the third-stage bias resistance previously established at 7 kilohms, the load impedance for the second stage should be 240 ohms. The power gain of the second stage, from equation 7, $G_2\cong$ 24.1 db, and second-stage input impedance, becomes approximately 780 ohms. This impedance is parallel with the second-stage base bias resistance of 10 kilohms, and provides a load impedance for the first stage of about 730 ohms. First-stage power gain for this load, $G_1\cong 29.4$ db. Input impedance is about 730 ohms. Including the shunting effect of the first-stage base bias resistances would result in an impedance of about 700 ohms being presented to the signal source. Total power gain for the three stages becomes the sum of the power gains of each stage and, for a 18.75-kilohm load, is 88.3 db, while for the selected 4-kilohm load it is about 85.2 db.

Phase shift in the direct-coupled amplifier is a combination of phase shifts introduced by the capacitance in the emitter circuits and the reactive loads of each stage. Equation 9 and Fig. 8 are used to obtain the voltage phase shift of each stage. For the first stage, $Z_e=15-j4$ and $Z_L=718-j104$. With values from Fig. 3

$$\frac{\Sigma_{T_1}}{\Sigma_{in_2}}=-(24.5\ \underline{/-1^\circ})$$

For the second stage

$$\frac{\Sigma_{T_2}}{\Sigma_{in_3}}=-(9.55\ \underline{/-2.5^\circ})$$

For the third stage, $Z_e=5-j4$. At the third-stage d-c operating level of 3 ma the transformer primary inductance is 3 henrys and primary impedance Z_L is about $250+j7{,}530$.

$$\frac{\Sigma_{T_3}}{\Sigma_{in_3}}=-(340\ \underline{/82^\circ})$$

Phase shift in the transformer coupling to the load, from equation 10 is approximately 23 degrees for the primary inductance of 3 henrys. Combining all angles phasorially as in Fig. 14 provides a resultant voltage phase shift for the 3-stage direct-coupled amplifier of −78 degrees.

Synopsis: An evaluation of the actual solutions exhibited by an electronic analogue computer, and thus a measure of its accuracy and stability, requires the analysis of a physical system represented by a linear differential equation system of higher order than that of the mathematical problem being solved. To this situation the powerful and systematic methods of matrix analysis are applied, yielding expressions from which the degree of accuracy which may be attained in computer solutions may be determined and, in particular, evaluating the all-important problems of stability of the electronic networks.

AN ELECTRONIC analogue computer programmed for a system of linear differential equations ideally exhibits solutions of the mathematical problem. Such a performance necessarily can be only approximated since idealizations cannot actually be achieved physically, for the networks in an electronic analogue machine are far more complex than the mathematical problem equations alone imply. To analyze so involved an electronic network systematically, a sufficiently general method of analysis is required.

The object of this paper is to apply the powerful and systematic methods of matrix analysis to determine more precisely the actual performance of the analogue machine. Clearly, analysis considering all physical parameters in the computer, while feasible and straightforward, is unnecessarily involved. This paper is therefore constrained to approximations which may be considered as first-order, and which yield a measure of the magnitude and nature of the approximations of the true mathematical solutions of the given problem, and to the all-important problem of stability. Furthermore, linearity of the system is presumed in this analysis. The matrix approach is, however, completely general and higher-order approximations could be determined if desired.

Basic Electronic Computer Matrices

The basic electronic computer networks are shown in Fig. 1(A) and (B), in which μ_1 and μ_2 represent multistage electronic amplifiers and the y_{ii} are primitive dinodes, i.e., capacitors and conductances or their combinations. These basic computer configurations are analyzed and synthesized on a common-node coordinate basis.

The n-stage amplifiers μ_1 and μ_2 are assumed to have admittance matrices $[y]$ of the following form

$$[y]=\begin{bmatrix} 0 & 0 \\ (-1)^{n+1}\dfrac{g_{m1}g_{m2}\cdots g_{m,n-1}g_{mn}}{(g_{p1}+y_{p1})(g_{p2}+y_{p2})\cdots(g_{p,n-1}+y_{p,n-1})} & (g_{pn}+y_{pn}) \end{bmatrix} \tag{1}$$

in which the g_m:*s* and g_p:s are the mutual and plate conductances respectively, while the y_P:*s* represent the frequency-dependent dinode interstage networks. This equation may be abbreviated as

$$[y]=\begin{bmatrix} 0 & 0 \\ \mu_0(d)g_{mn} & (g_{pn}+y_{pn}) \end{bmatrix} \tag{2}$$

in which the frequency dependence and voltage amplification of the interstage networks is represented by $\mu_0(d)$, where $d=d/dt$. In this analysis, n is considered an odd number.

The y-matrix of the entire network of Fig. 1(A), or 1(B), may be obtained from the sum of equation 2 and the y-matrices for the dinode admittances y_{rk} which have the form

$$[y]=\begin{bmatrix} y_{rk} & -y_{rk} \\ -y_{rk} & y_{rk} \end{bmatrix} \tag{3}$$

Conventional matrix operations will yield the matrices of the complete networks. For Fig. 1(A) this may be readily verified as

$$[y]=\begin{bmatrix} \dfrac{y_{11}(\mu_0(d)\times g_{mn}+(g_{pn}+y_{pn})+y_{21})}{(g_{pn}+y_{pn})+y_{11}+y_{21}} & \dfrac{-y_{11}y_{21}}{(g_{pn}+y_{pn})+y_{11}+y_{21}} \\ \dfrac{y_{21}(\mu_0(d)\times g_{mn}-y_{11})}{(g_{pn}+y_{pn})+y_{11}+y_{21}} & \dfrac{y_{21}((g_{pn}+y_{pn})+y_{11})}{(g_{pn}+y_{pn})+y_{11}+y_{21}} \end{bmatrix} \tag{4}$$

Although the complete network performance may be obtained from this general matrix, the inclusion of all the terms indicated in equation 4 results in more involved computations than warranted. The principal idealization introduced to simplify this expression is that of postulating indefinitely large output admittance in the amplifier, or

$$g_{pn}\rightarrow\infty \tag{5}$$

By noting further that

$$g_{mn}=g_{pn}\times\mu_{0n} \tag{6}$$

where μ_{0n} is the voltage amplification factor of the last stage, equation 4 may be approximated by

$$[y]=\begin{bmatrix} y_{11}(\mu_0(d)\times\mu_{0n}+1) & 0 \\ y_{21}\times\mu_0(d)\times\mu_{0n} & y_{22} \end{bmatrix} \tag{7}$$

By further defining for compactness

$$\mu_0(d)\times\mu_{0n}\equiv\mu_1(d)\equiv\mu_1 \tag{8}$$

equation 7 becomes

$$[y]=\begin{bmatrix} y_{11}\times(\mu_1+1) & 0 \\ y_{21}\times\mu_1 & y_{22} \end{bmatrix} \tag{9}$$

It is convenient to rewrite equation 9 in the following manner

$$[y]=\begin{bmatrix} y_{11}\times\mu_1 & 0 \\ y_{21}\times\mu_1 & 0 \end{bmatrix}+\begin{bmatrix} y_{11} & 0 \\ 0 & y_{22} \end{bmatrix} \tag{10}$$

The reason for the partitioning of equation 9 into the form of equation 10 (correspondingly for equation 11) is that as will be shown subsequently, a transformation of the first part will place it in 1-to-1 correspondence with the mathematical problem, leaving the second part as the principal source of error in the computer system.

The network of Fig. 1(B) may be analyzed similarly, and its y-matrix verified as

$$[y]=\begin{bmatrix} 0 & y_{12}\times\mu_2 \\ 0 & y_{22}\times\mu_2 \end{bmatrix}+\begin{bmatrix} y_{12} & 0 \\ 0 & y_{22} \end{bmatrix} \tag{11}$$

Although it is possible to formulate an electronic network synthesis of mathematical problems based upon these simple networks, it is advantageous to consider their generalization, Fig. 2.

This paper summarizes some of the researches reported in a doctoral dissertation submitted by the junior author to the Sever Institute of Technology of Washington University.

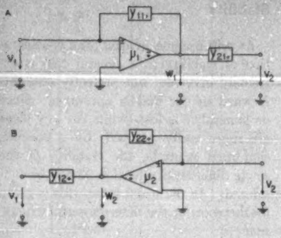

Fig. 1. Basic electronic synthesis networks

The representation in Fig. 2 includes amplifiers with bipolar output polarities, and additional dinode admittances y_{sk}. The admittance matrix of this generalized electronic network, following the pattern of equations 10 and 11, then reads

$$[y]=\begin{bmatrix} 0 \,.\, 0 & (y_{1k+}-y_{1k-})\mu_k & 0 \,.\, 0 \\ 0 \,.\, 0 & (y_{2k+}-y_{2k-})\mu_k & 0 \,.\, 0 \\ \cdots & \cdot \quad \cdot \quad \cdot & \cdots \\ 0 \,.\, 0 & (y_{kk+}-y_{kk-})\mu_k & 0 \,.\, 0 \\ \cdots & \cdot \quad \cdot \quad \cdot & \cdots \\ 0 \,.\, 0 & (y_{rk+}-y_{rk-})\mu_k & 0 \,.\, 0 \\ 0 \,.\, 0 & (y_{sk+}-y_{sk-})\mu_k & 0 \,.\, 0 \end{bmatrix}+\begin{bmatrix} (y_{1k+}+y_{1k-}) & . & 0 & . & 0 \\ 0 & . & 0 & . & 0 \\ . & . & . & . & . \\ 0 & . & (y_{kk+}+y_{kk-}) & . & 0 \\ . & . & . & . & . \\ 0 & . & 0 & . & 0 \\ 0 & . & 0 & . & (y_{sk+}+y_{sk-}) \end{bmatrix} \tag{12}$$

The first part of equation 12 is called the ideal synthesis matrix, because it can be placed in 1-to-1 correspondence with the mathematical problem to be solved, after a transformation. The second part is called the network error matrix; this is of diagonal form and one of the sources of error in the computer.

In addition to the network error matrix, additional matrix terms indicating the errors due to approximations of ideal current sources by equivalent voltage sources and series impedances, and due to parasitic parameters in the physical network may also be important. The terms in the equivalent source error matrix appear on the principal diagonal, and are primarily conductances. Parasitic elements may be present in all the matrix entries, but those which predominate are usually capacitive terms also on the principal diagonal, and often due to shielded input leads to the amplifiers.

Thus, the matrix admittance equations for a general ($s \times s$) order computing network may be represented by the following:

$$([1_y]+[2_y]+[3_y]+[4_y])\begin{bmatrix} v_1 \\ v_2 \\ . \\ v_k \\ . \\ v_r \\ v_s \end{bmatrix}=\begin{bmatrix} j_1' \\ j_2' \\ . \\ j_k' \\ . \\ j_r' \\ j_s' \end{bmatrix} \tag{13}$$

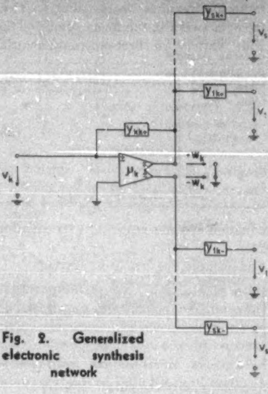

Fig. 2. Generalized electronic synthesis network

in which the ideal synthesis matrix now is

$$[1_y]=\begin{bmatrix} (y_{11+}-y_{11-})\mu_1 & . \; . & (y_{1k+}-y_{1k-})\mu_k & . \; . & (y_{1s+}-y_{1s-})\mu_s \\ (y_{21+}-y_{21-})\mu_1 & . \; . & (y_{2k+}-y_{2k-})\mu_k & . \; . & (y_{2s+}-y_{2s-})\mu_s \\ . & . \; . & . & . \; . & . \\ (y_{k1+}-y_{k1-})\mu_1 & . \; . & (y_{kk+}-y_{kk-})\mu_k & . \; . & (y_{ks+}-y_{ks-})\mu_s \\ . & . \; . & . & . \; . & . \\ (y_{r1+}-y_{r1-})\mu_1 & . \; . & (y_{rk+}-y_{rk-})\mu_k & . \; . & (y_{rk+}-y_{rs-})\mu_s \\ (y_{s1+}-y_{s1-})\mu_1 & . \; . & (y_{sk+}-y_{sk-})\mu_k & . \; . & (y_{ss+}-y_{ss-})\mu_s \end{bmatrix} \tag{14}$$

and the network error matrix is

$$[2_y]=\begin{bmatrix} \sum_{t=1}^{s}(y_{1t+}+y_{1t-}) & . & 0 & . & 0 \\ 0 & . & 0 & . & 0 \\ . & . & . & . & . \\ 0 & . & \sum_{t=1}^{s}(y_{kt+}+y_{kt-}) & . & 0 \\ . & . & . & . & . \\ 0 & . & 0 & . & 0 \\ 0 & . & 0 & . & \sum_{t=1}^{s}(y_{st+}+y_{st-}) \end{bmatrix} \tag{15}$$

The equivalent source error matrix $[3_y]$ and the predominant parasitic (capacitive) error matrix $[4_y]$ are both diagonal in form, as previously stated, and may or may not be significant, depending upon the particular computing machine. Finally, the right-hand column of j_s':s in equation 13 represents the current-source equivalents constructed from intrinsic voltage-sources and series impedances.

Applying to equation 13 the transformation

$$[v]=C[-w] \tag{16}$$

where

$$C=\begin{bmatrix} \frac{1}{\mu_1} & 0 & . \; 0 & . \; 0 & 0 \\ 0 & \frac{1}{\mu_2} & . \; 0 & . \; 0 & 0 \\ . & . & . \; . & . \; . & . \\ 0 & 0 & . \; \frac{1}{\mu_k} & . \; 0 & 0 \\ . & . & . \; . & . \; . & . \\ 0 & 0 & . \; 0 & . \; \frac{1}{\mu_r} & 0 \\ 0 & 0 & . \; 0 & . \; 0 & \frac{1}{\mu_s} \end{bmatrix} \tag{17}$$

results in

$$([0_y]+[2_y]C+[3_y]C+[4_y]C)\begin{bmatrix} -w_1 \\ -w_2 \\ . \\ -w_k \\ . \\ -w_r \\ -w_s \end{bmatrix}=\begin{bmatrix} j_1' \\ j_2' \\ . \\ j_k' \\ . \\ j_r' \\ j_s' \end{bmatrix} \tag{18}$$

It should be noted that the *-w*:*s* represent the actual amplifier output voltages.

In equation 18 the term

$$[0_y]=[1_y]C \tag{19}$$

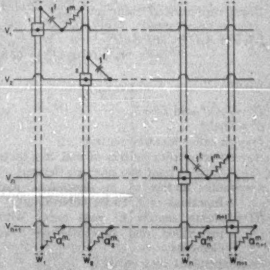

Fig. 3 (right). Ideograph of synthesis network according to equation 25, exhibiting solution to equation 23 which will be shown to correspond exactly to the mathematical problem matrix, now reads

$$[{}^0_y]=\begin{bmatrix} (y_{11+}-y_{11-}) & \cdot\ \cdot & (y_{1k+}-y_{1k-}) & \cdot\ \cdot & (y_{1s+}-y_{1s-}) \\ (y_{21+}-y_{21-}) & \cdot\ \cdot & (y_{2k+}-y_{2k-}) & \cdot\ \cdot & (y_{2s+}-y_{2s-}) \\ \cdot & \cdot\ \cdot & \cdot & \cdot\ \cdot & \cdot \\ (y_{k1+}-y_{k1-}) & \cdot\ \cdot & (y_{kk+}-y_{kk-}) & \cdot\ \cdot & (y_{ks+}-y_{ks-}) \\ \cdot & \cdot\ \cdot & \cdot & \cdot\ \cdot & \cdot \\ (y_{r1+}-y_{r1-}) & \cdot\ \cdot & (y_{rk+}-y_{rk-}) & \cdot\ \cdot & (y_{rs+}-y_{rs-}) \\ (y_{s1+}-y_{s1-}) & \cdot\ \cdot & (y_{sk+}-y_{sk-}) & \cdot\ \cdot & (y_{ss+}-y_{ss-}) \end{bmatrix} \tag{20}$$

and no longer exhibits the amplifier gains the μ:s.

The numerically small entries in the matrices $[{}^2_y]C$, $[{}^3_y]C$, $[{}^4_y]C$, resulting from large magnitude μ_k, do not assure stability of the computer network. In a qualitative sense, the fact that these terms are "small" usually results in "high-frequency" stability problems. Clearly, the mathematical problem stability, indicated by the properties of $[{}^0_y]$ alone, is entirely distinct from the electronic network stability, which is determined by all four matrix terms in equation 18.

Furthermore, each allowable transformation of the mathematical problem and synthesis matrices represents a new and distinct electronic network due to the error matrices, although exhibiting, ideally, the same mathematical solution. Since the stability of the electronic network depends on all terms of equation 18 and not on the synthesis matrix $[{}^0_y]$ alone, each such transformation may yield either a stable or an unstable electronic network. This acts as an undesired constraint on the type of equivalent mathematical system which may be synthesized on any given computer.

Mathematical Problem Matrices

It has been shown[1] that the synthesis matrix $[{}^0_y]$, equation 20, may be placed in 1-to-1 correspondence with the matrix representation of a differential equation system. This means, briefly, that programming an electronic analogue computer for a system of differential equations, represented compactly as

$$(A_1D^0+A_2D+\ldots+A_nD^{n-1}+A_{n+1}D^n)x=f(t) \tag{21}$$

where

$D^n=I\times d^n$ and $D^0=I$

$d^n=d^n/dt^n$

$I=m$th order identity matrix

$A_i=$an mth order matrix of real constants with at least one nonzero element

$x=$column matrix of m dependent real functions of t, to be determined

$f(t)=$column matrix of mth order with prescribed real functions of t as elements

$t=$independent real variable

in reality requires synthesizing an electronic network in the image of one of the wide variety of first-order differential equation systems equivalent to equation 21.

For example, the first-order system

$$\begin{bmatrix} D & -I & 0 & \cdot\ \cdot & 0 & 0 \\ 0 & D & -I & \cdot\ \cdot & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot\ \cdot & \cdot & \cdot \\ 0 & 0 & 0 & \cdot\ \cdot & D & -I \\ A_1 & A_2 & A_3 & \cdot\ \cdot & A_n & A_{n+1} \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \\ \cdot \\ x_n \\ x_{n+1} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \cdot \\ 0 \\ f(t) \end{bmatrix} \tag{22}$$

in which $x_i=D^{i-1}x$, $i=1,\ldots,n,n+1$ yields the solutions to the given problem equation 21 which represents a system in m variables, with at least one of the equations of the nth order.

A single nth order equation such as

$$(a_1+a_2d+\ldots+a_nd^{n-1}+a_{n+1}d^n)x=0 \tag{23}$$

may similarly be represented as

$$\begin{bmatrix} d & -1 & 0 & 0 & \cdot & 0 & 0 \\ 0 & d & -1 & 0 & \cdot & 0 & 0 \\ 0 & 0 & d & -1 & \cdot & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & 0 & 0 & \cdot & d & -1 \\ a_1 & a_2 & a_3 & a_4 & \cdot & a_n & a_{n+1} \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ \cdot \\ x_n \\ x_{n+1} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \cdot \\ 0 \\ 0 \end{bmatrix} \tag{24}$$

The synthesis matrix $[{}^0_y]$ for the problem equation 23 in this instance reads

$$\begin{bmatrix} c_{11}d & -g_{12} & 0 & \cdot\ \cdot & 0 & 0 \\ 0 & c_{22}d & -g_{23} & \cdot\ \cdot & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot\ \cdot & \cdot & \cdot \\ 0 & 0 & 0 & \cdot\ \cdot & c_{nn}d & -g_{n,n+1} \\ g_{n+1,1} & g_{n+1,2} & g_{n+1,3} & \cdot\ \cdot & g_{n+1,n} & g_{n+1,n+1} \end{bmatrix} \begin{bmatrix} -w_1 \\ -w_2 \\ \cdot \\ -w_n \\ -w_{n+1} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \cdot \\ 0 \\ 0 \end{bmatrix} \tag{25}$$

in which the c:s are capacitances, and the g:s conductances located in the network as indicated by their ordering numerical subscripts. Initially, the actual numerical magnitude of these dinode elements (usually in the microfarad and micromho range) are determined by the numerical coefficients of the original differential equation and the transformations indicated. However, as shown in the reference,[1] there is a wide latitude for the magnitude of these coefficients, the choice depending actually upon the characteristics of the particular computer.

Although the electronic network synthesis is inherent in the matrix notation, a symbolic network representation of equation 25 is denoted in the ideograph Fig. 3, as a practical convenience.

Stability

As will become evident, the consideration of stability in a general case is extremely involved, but perfectly straightforward by the matrix approach. Since no generality is lost (while the key ideas are more easily grasped) by a specific, simplified example, the stability of the single differential equation 23 will be considered. In the usual sense, this is given by the roots of the determinantal expression

$$a_1+a_2\lambda+\ldots+a_n\lambda^{n-1}+a_{n+1}\lambda^n=0 \tag{26}$$

which may be abbreviated to read

$$\Delta(\lambda)=0 \tag{27}$$

A single λ-root of equation 26 with a positive real part indicates that the mathematical solution, in which $x_i=X_ie^{\lambda t}$ represents a typical term, is unstable; conversely, if all roots of equation 26 have negative real parts the mathematical problem solution is stable. These considerations, however, do not guarantee the stability of the electronic computer network synthesized to exhibit the solution to the problem.

To simplify the discussion of the stability of the synthesized electronic network, it is convenient to consider the dinode network parameters shown in Fig. 3 to be in farads and mhos. Thus, equation 25 will read

$$\begin{bmatrix} d & -1 & \cdot\ \cdot & 0 & 0 \\ 0 & d & \cdot\ \cdot & 0 & 0 \\ \cdot & \cdot & \cdot\ \cdot & \cdot & \cdot \\ 0 & 0 & \cdot\ \cdot & d & -1 \\ a_1 & a_2 & \cdot\ \cdot & a_n & a_{n+1} \end{bmatrix} \begin{bmatrix} -w_1 \\ -w_2 \\ \cdot \\ -w_n \\ -w_{n+1} \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \cdot \\ 0 \\ 0 \end{bmatrix} \tag{28}$$

and the mathematical and synthesis matrices become identical numerically.

Fig. 9 (right). Ideograph of synthesis network exhibiting solution of $(1+d^2)x=0$ on experimental computer, according to equation 39

GEDA	(n) self-d
(n+1) self-d	(n) mutual-d
(n+1) mutual-d	(n+1 mixed-d

Corresponding to the ideal synthesis matrix shown in equation 28, the complete electronic network admittance matrix comprises four distinct matrix terms, since the electronic network is more complicated than the mathematical matrix would indicate. For simplicity and without loss of generality, only the first two terms of equation 18 will be considered in the determination of the nature of the electronic network stability (the other terms can easily be included in a numerical case, but are rather clumsy if included in the following general expressions). The two terms are the synthesis matrix shown above, or

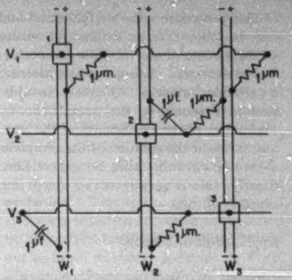
$$[0_y]=\begin{bmatrix} d & -1 & \cdot & 0 & 0 \\ 0 & d & \cdot & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & 0 & \cdot & d & -1 \\ a_1 & a_2 & \cdot & a_n & a_{n+1} \end{bmatrix} \tag{29}$$

and the network error matrix

$$[2_y]=\begin{bmatrix} (d+1)\frac{1}{\mu_1} & 0 & \cdot & 0 & 0 \\ 0 & (d+1)\frac{1}{\mu_2} & \cdot & 0 & 0 \\ \cdot & & \cdot & \cdot & \cdot \\ 0 & 0 & \cdot & (d+1)\frac{1}{\mu_n} & 0 \\ 0 & 0 & \cdot & 0 & \sum_{i=1}^{n+1}|a_i|\,\frac{1}{\mu_{n+1}} \end{bmatrix} \tag{30}$$

The stability of the electronic network, under these simplifications, is determined by the roots of the determinant of the sum of the matrices 29 and 30, that is by

$$\left\|\begin{bmatrix} \lambda+(\lambda+1)\frac{1}{\mu_1} & -1 & \cdot & 0 & 0 \\ 0 & \lambda+(\lambda+1)\frac{1}{\mu_2} & \cdot & 0 & 0 \\ \cdot & & \cdot & & \cdot \\ 0 & 0 & \cdot & \lambda+(\lambda+1)\frac{1}{\mu_n} & -1 \\ a_1 & a_2 & \cdot & a_n & a_{n+1}+\sum_{i=1}^{n+1}|a_i|\frac{1}{\mu_{n+1}} \end{bmatrix}\right\|=0 \tag{31}$$



The λ-roots of equation 31 are now the exponents of the exponential terms of the solution of the differential equation of the complete electronic network. Reduction of the determinant 31 yields the compact expression

$$\Delta\left(\lambda+(\lambda+1)\frac{1}{\mu}\right)+\sum_{i=1}^{n+1}|a_i|\frac{1}{\mu}\left(\lambda+(\lambda+1)\frac{1}{\mu}\right)^n=0 \tag{32}$$

in which it should be noted that $\Delta()$ is defined by equation 27, and all μ_i are taken as equal for simplicity.

It is evident that equation 32 is far more complex than the determinantal equation 27 of the original differential equation 23. Furthermore, the nature of the λ-roots of equation 32, which determine the stability of the complete electronic network depends not only upon the original problem but also upon the choice of first-order system used to represent it, and finally upon the amplifier characteristics, the $\mu_i(d)$.

This procedure is perfectly general and may be followed to investigate the nature of the λ-roots of any of the various electronic networks chosen for synthesizing a particular problem. Of course, in addition to determining the actual λ-roots, evaluation of the coefficients of the various terms of the solution of the complete electronic network could be undertaken. Clearly, this is very involved except for simplest of cases.

Application of Theory

Application of the foregoing theory can be illustrated by the simple differential equation

$$(1+d^2)x=0 \tag{33}$$

Of the indefinitely large variety of representations in which this equation may be programmed for synthesis on an analogue computer, the following six equivalent first-order systems may be classed as typical. These examples will also illustrate the method of application of the synthesis and error matrices to the study of the stability of electronic computer networks. It is important to note that most of the electronic networks corresponding to the synthesis matrices of the following first-order systems are not accessible by the techniques heretofore available in the art.

The first-order systems chosen are given in equations 34 through 39. The corresponding computer programming of these examples is illustrated by the ideographs in Figs. 4 through 9 respectively. The descriptive titles of the various synthesis matrices refer to the location of the differential terms, the *d:s*, represented in the ideographs by the capacitance symbols.

GEDA L3

$$\textit{GEDA}\quad \begin{bmatrix} d & 1 & 0 \\ 0 & d & 1 \\ 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} -w_1 \\ +w_2 \\ -w_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{34}$$

EXPERIMENTAL COMPUTER

$$(n+1)\ \text{self-}d\quad \begin{bmatrix} d & -1 & 0 \\ 0 & d & -1 \\ 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} -w_1 \\ -w_2 \\ -w_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{35}$$

$$(n+1)\ \text{mutual-}d\quad \begin{bmatrix} 1 & 0 & 1 \\ -d & 1 & 0 \\ 0 & -d & 1 \end{bmatrix} \begin{bmatrix} -w_1 \\ -w_2 \\ -w_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{36}$$

$$(n)\ \text{self-}d\quad \begin{bmatrix} d & -1 \\ 1 & d \end{bmatrix} \begin{bmatrix} -w_1 \\ -w_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{37}$$

$$(n)\ \text{mutual-}d\quad \begin{bmatrix} 1 & d \\ -d & 1 \end{bmatrix} \begin{bmatrix} -w_1 \\ -w_2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{38}$$

$$(n+1)\ \text{mixed-}d\quad \begin{bmatrix} 1 & 0 & 1 \\ 0 & d & -1 \\ -d & 1 & 0 \end{bmatrix} \begin{bmatrix} -w_1 \\ -w_2 \\ -w_3 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix} \tag{39}$$

The solution to equation 33 may be written in the form

$$x=X_1\epsilon^{\lambda_1 t}+X_2\epsilon^{\lambda_2 t} \tag{40}$$

in which the *λ:s* are given by the roots of the determinantal equation

$$|1+\lambda^2|=0 \tag{41}$$

which yields for the λ-roots

$$\lambda=\pm i \tag{42}$$

Clearly, each programming of equation 33 yields the same determinantal equation and the same λ-roots, so that the solutions obtained from equations 34 through 39 are identical to that given by equation 41, namely, that $\lambda=\pm i$.

However, this ideal mathematical situation does not exist in the physical computer. Although the mathematical solution 40 is bounded, most of the synthesis matrices yield unstable electronic networks with conventional computers. To reiterate, the stability of the computer network is not indicated by the synthesis matrices alone.

$$\textit{GEDA}\quad \left\| \overset{\text{Synthesis}}{\begin{bmatrix} \lambda & 1 & 0 \\ 0 & \lambda & 1 \\ 1 & 0 & 1 \end{bmatrix}} + \overset{\text{Error}}{\begin{bmatrix} (\lambda+1)\frac{1}{\mu_a} & 0 & 0 \\ 0 & (\lambda+1)\frac{1}{\mu_b} & 0 \\ 0 & 0 & (2)\frac{1}{\mu_c} \end{bmatrix}} \right\| = 0 \tag{43}$$

$$(n+1)\ \text{self-}d\quad \left\| \begin{bmatrix} \lambda & -1 & 0 \\ 0 & \lambda & -1 \\ 1 & 0 & 1 \end{bmatrix} + \begin{bmatrix} (\lambda+1)\frac{1}{\mu} & 0 & 0 \\ 0 & (\lambda+1)\frac{1}{\mu} & 0 \\ 0 & 0 & (2)\frac{1}{\mu} \end{bmatrix} \right\| = 0 \tag{44}$$

$$(n+1)\ \text{mutual-}d\quad \left\| \begin{bmatrix} 1 & 0 & 1 \\ -\lambda & 1 & 0 \\ 0 & -\lambda & 1 \end{bmatrix} + \begin{bmatrix} (2)\frac{1}{\mu} & 0 & 0 \\ 0 & (\lambda+1)\frac{1}{\mu} & 0 \\ 0 & 0 & (\lambda+1)\frac{1}{\mu} \end{bmatrix} \right\| = 0 \tag{45}$$

$$(n)\ \text{self-}d\quad \left\| \begin{bmatrix} \lambda & -1 \\ 1 & \lambda \end{bmatrix} + \begin{bmatrix} (\lambda+1)\frac{1}{\mu} & 0 \\ 0 & (\lambda+1)\frac{1}{\mu} \end{bmatrix} \right\| = 0 \tag{46}$$

$$(n)\ \text{mutual-}d\quad \left\| \begin{bmatrix} 1 & \lambda \\ -\lambda & 1 \end{bmatrix} + \begin{bmatrix} (\lambda+1)\frac{1}{\mu} & 0 \\ 0 & (\lambda+1)\frac{1}{\mu} \end{bmatrix} \right\| = 0 \tag{47}$$

$$(n+1)\ \text{mixed-}d\quad \left\| \begin{bmatrix} 1 & 0 & 1 \\ 0 & \lambda & -1 \\ -\lambda & 1 & 0 \end{bmatrix} + \begin{bmatrix} (2)\frac{1}{\mu} & 0 & 0 \\ 0 & (\lambda+1)\frac{1}{\mu} & 0 \\ 0 & 0 & (\lambda+1)\frac{1}{\mu} \end{bmatrix} \right\| = 0 \tag{48}$$

Thus, the actual λ-roots of the programmed systems, as indicated in the previous section, may be obtained from the determinantal equations 43 through 48. These include not only the synthesis matrices but also the respective error matrices for each of the equivalent systems.

* Amplifier characteristics of the experimental laboratory computer were designed and measured such that $k=1{,}000$ and $\tau=0.01$, except for case $(n+1)$ mixed-d which had $k=1{,}000$ and $\tau=1.0$.

It is helpful at this stage to consider actual numerical results, particularly for a comparison of the theory with physical systems. Accordingly the coefficients in the matrices 34 through 39, and 43 through 48, were taken to represent micromhos and microfarads. The λ-roots of the determinantal equations 44 through 48 were then computed and are listed in Table I. No computations were made for equation 43 since the amplifier characteristics μ_a, μ_b, and μ_c were unknown.

The computed λ-roots were then compared with physically measured λ-roots obtained with a laboratory-type electronic analogue computer. This computer was designed with carefully controlled amplifier characteristics, the $\mu_i(d)$, expressible over the range of interest of the variables by the equation

$$\pm W=\mu V \tag{49}$$

$$\mu(d)=\frac{k}{\tau d+1} \tag{50}$$

Equation 50 may be recognized as representing a linear amplifier with a gain k, a single resistance-capacitance $=\tau$ cutoff, a single input V, and bipolar outputs $+W$ and $-W$. The same $\mu(d)$ characteristics were of course assigned in the computations of the λ-roots from equations 44 through 48.

The experimentally measured λ-roots determined from the oscillographic records obtained with the laboratory computer are also listed in Table I. As may be noted, the agreement between computed and measured λ-roots is well within experimental errors, particularly in view of the 10 per cent tolerance of all dinode elements (conductances and capacitances) utilized in the experimental computer. Included in this table are measured λ-roots obtained with a *GEDA L3* computer (Goodyear Aircraft Corporation) programmed according to equation 34.

The initial portions of the oscillograms of the solutions of equation 33 taken with the *GEDA* and the laboratory computers are shown in Fig. 10. The oscillograms show solutions (for identical initial conditions) according to the programming equations 34 through 39, and ideographs Figs. 4 through 9 respectively. Clearly, all the systems yield substantially identical solutions to equation 33, with one exception. This is the $(n+1)$ mutual-d synthesis, equation 36, which as predicted by the determinantal expression 45 turns out to be an unstable electronic network. This is confirmed physically by the corresponding oscillographic record for this case in Fig. 10.

It may be noted from the oscillographic records that the decay of the amplitude of the solution obtained with the laboratory computer (a sensitive test) compares not unfavorably with the solution obtained with the *GEDA* computer, although the experimental computer gain $k=1{,}000$ is far less than the quoted gain of the *GEDA*. Finally, it may be inferred from the oscillograms that the error matrices have but a negligible effect upon the magnitude of the coefficients of the solution, although all-important in so far as the electronic network stability is concerned.

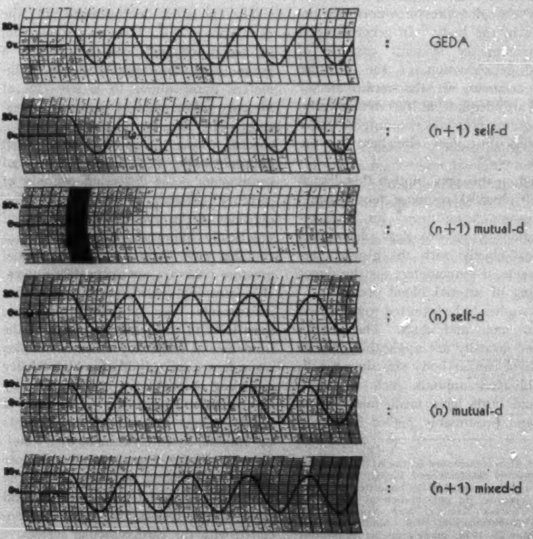

Fig. 10. Oscillograms of solutions of $(1+d^2)x=0$ displayed by GEDA and experimental computer. Sensitivity 2 volts per millimeter; chart speed 5 millimeters per second

Conclusions

The application of matrix methods provides a rational and powerful method of analysis of electronic analogue computer networks. The matrix method is completely general, and may be applied not only to the study of computer stability but also to other problems such as the actual evaluation of the magnitude of the coefficients of the solution as well as the determination of the λ-roots of the electronic network; the study of the best amplifier characteristics for computer applications; the effects of precision of network components, and of stray parameters. The latter is not unimportant, particularly for matrices with zero entries on their principal diagonal, such as in the synthesis matrix in equation 39.

Other attributes of the matrix method may be found in reference 1.

Physical Response Requirements of Pressure Transducers for the Reproduction of Physiological Phenomena

E. H. WOOD
NONMEMBER AIEE

THE pressure variations generated by the heart beat are perhaps the most rapidly changing pressures normally occurring in the body. In general therefore manometer systems capable of faithful reproduction of the pressure pulses occurring in the cardiovascular system are adequate, at least dynamically, for recording pressures encountered under usual circumstances elsewhere in the body.

Based on this presumption this discussion of physical response requirements of pressure transducers for the reproduction of physiological phenomena will deal chiefly with the physical requirements of manometers for the direct recording of arterial blood pressure.

The studies to be reported were carried out on men and dogs. The results obtained actually are applicable only to animals of similar body size since small, warm-blooded animals such as mice, rats, and birds have much faster heart rates and presumably higher frequency variations in blood pressure than those encountered in man.

The pressures encountered in the circulation and the body as a whole will, in nearly all instances, fall within a range from approximately 300 millimeters (mm) above to a few mm of mercury below ambient barometric pressure. The sensitivity required in recording these pressures varies from approximately 1 mm up to several centimeters' (cm) deflection per mm of mercury pressure. The highest frequencies of the dynamic components of practically important magnitudes in a complex wave form such as an arterial pressure pulse are not accurately known. It is generally considered, however, that instruments with a uniform dynamic sensitivity to the tenth harmonic of the fundamental frequency of such complex wave forms are suitable for high-fidelity recording of the wave concerned.[1] By this criterion, since the heart rate of human beings seldom exceeds 240 beats per minute, as an instrument with a uniform sensitivity from 0 to 40 cycles per second (cps) should be adequate for the recording of arterial blood pressure and most other physiological variables associated with the cardiovascular system.

It should be emphasized that certain requirements of manometer systems are equally or more important than are the dynamic characteristics. These are: high stability, linear calibration, usability with long leads, insensitivity to movement, temperature humidity and acceleration, imperviousness to electrolyte solutions, simplicity of operation, and construction for ease of sterilization and removal of air bubbles entrapped in the hydraulic system. Of these requirements high stability and simplicity of operation are, from a practical viewpoint, of greatest importance. It is of little value for a manometer to have extremely good dynamic characteristics, allowing reproduction of the fastest dynamic components of the pressure pulses, if instability of its base line or of its sensitivity results in errors in recorded pressures of greater magnitude than the relatively small dynamic components of the pressure wave which it is capable of reproducing.

Although it is generally agreed that a manometer system with uniform sensitivity from 0 to 50 cps will accurately reproduce arterial pulse waves,[2] there are no direct data in the literature concerning how much this dynamic response can be decreased without producing significant distortion of the recorded pulse wave. This is a practically very important question, especially in reference to direct blood pressure studies in human beings. It determines, for any given manometer system, the minimal dimensions of hypodermic needles or catheters that must be introduced into the vascular system in order to permit accurate recording of pressures therefrom. The desirability of using the smallest possible needles and catheters when studies are carried out on unanesthetized human beings is obvious.

The remainder of this presentation will be devoted to this problem of the minimal dynamic response characteristics of manometer systems required for adequate recording of vascular pressure pulses in man.[3]

Paper 56-81, recommended by the AIEE Electrical Techniques in Medicine and Biology Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted May 25, 1953; made available for printing December 1, 1955.

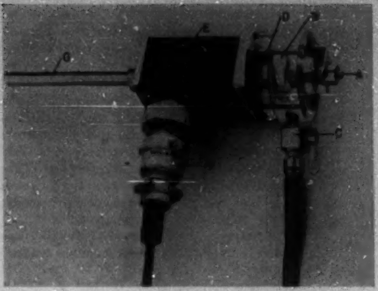

Fig. 1. Strain-gauge manometer, Statham model P6-15G-250, adapted for physiological studies

By permission of Science, Washington, D. C.

Fig. 3. Apparatus for testing dynamic response of manometer systems by subjecting them to square-wave pressure change[9]

The perfection of electric manometers for recording pressures simplifies the collection of direct data on this point since it is a simple matter to change the over-all dynamic response of such manometers rapidly and reproducibly. Strain-gauge[4] capacitance[5] and variable reluctance[6,7] pressure transducers were used in these studies. Of these the unbonded strain-gauge manometers, because of their stability and simplicity of operation, proved the most useful.

Such a manometer is illustrated in Fig. 1. The hypodermic Luer-lok fitting for attachment of needles or catheters is fitted onto a lucite housing specially constructed for ease of detection and removal of entrapped air bubbles. The stopcock allows flushing of the manometer chamber and attachments with sterile saline solution. The electric connections consist of two pairs of leads, one pair of which connects to a source of direct current for maintaining a constant voltage across the strain-gauge wheatstone bridge circuit and the other connects to a high-performance oscillographic galvanometer which records the output of the strain gauge without electronic amplification.

Fig. 2. Experimental setup used for studying the minimal dynamic response characteristics of manometer systems necessary for recording peripheral arterial pressure pulses in man

At *A* in Fig. 1, is shown the Luer-lok fitting for attachment of hypodermic needles, venous or arterial catheters and the like. At *B* is the lucite chamber filled with sterile saline solution containing an anticoagulant (heparin, 40 milligram per liter); this solution can be flushed through the attached needle or catheter by opening stopcock *C* to a pressurized wash bottle reservoir containing the solution. At *D* is the lucite chamber filled with oil and containing the pressure-sensing diaphragm of the manometer; chambers *D* and *B* are separated by a passive diaphragm of polythene, 0.006 inch thick. At *E* is the housing of the Statham strain-gauge unit; At *F* is the electric connector to the indicating-galvanometer circuit and d-c source. At *G* is the rod for mounting the manometer. The lucite chamber *B* is dome-shaped and polished for ease of visualization and the removal of entrapped air bubbles.

A manometer assembly commonly used in laboratories for continuous recording of arterial pressure[8,9] consists of a 20-gauge needle connected to a glass hypodermic adapter, thence to a 25-cm length of polythene tubing (0.085-inch inside diameter (ID), 0.135-inch outside diameter), connected to the strain gauge via a 2-way stopcock; see Fig. 2. The stopcock makes possible withdrawal of arterial blood samples from the same needle through which arterial pressure is recorded.[8]

In Fig. 2 the two strain-gauge manometer systems are connected to indwelling needles in the radial and brachial arteries. The needles are kept free from clot formation by frequent flushing with heparinized saline solution contained in the reservoir wash bottle system which is pressurized by the hand-bulb Tycos manometer assembly. The zero reference point for the manometers is established by opening them to the wash bottle when its meniscus is at midchest level. The manometers are calibrated *in situ* and simultaneously in a similar fashion by applying known pressures above the fluid level in the wash bottle. One manometer system is used to monitor the arterial pressure pulses continuously when the effects of variation of dynamic response of the second manometer on the pressure pulse recorded by that manometer are under study.

The dynamic response characteristics of such a manometer assembly are rather difficult to predict since it cannot be considered certain that the well-established frequency-damping relationships which apply to a simple instrument with one degree of freedom would be applicable to a heterogeneous assembly such as this or

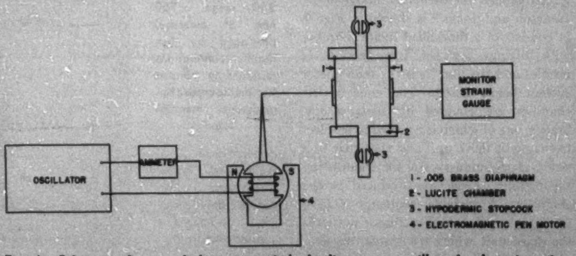

Fig. 4. Schematic diagram of electromagnetic hydraulic-pressure oscillator for dynamic testing of manometer systems

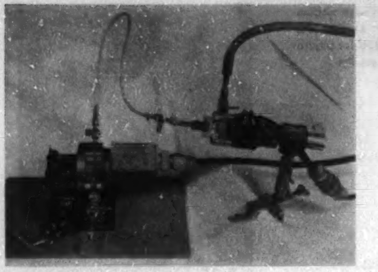

Fig. 5. Pressure changer assembly of electromagnetic hydraulic pressure oscillator

many of the other more or less complicated manometer assemblies commonly used in physiological studies.

Owing to this, and to the large variations in dynamic response caused by even minute air bubbles entrapped in the connections of the hydraulic system, it is important to have a convenient method of studying the dynamic response of such manometer systems and for checking this response at the time of their use. This can be done by recording the response of the system to a square-wave pressure change as illustrated in Fig. 3.

The needle of the manometer assembly is inserted into the fluid contained in a pressure chamber. The pressure in the air space over the fluid is increased by means of a hand bulb to just under the bursting pressure of the finger cot covering the pressure chamber. The balloon is then exploded with a blow torch, thus producing an instantaneous decrease to ambient pressure.[9]

However, if the manometer does not behave as a simple instrument it may not be possible to determine its dynamic characteristics from its response to a square-wave pressure change alone. Hydraulic pressure oscillators have been specially designed to study the response of such manometer systems to equal amplitude sine-wave pressure variations of variable frequency. A schematic diagram of such an oscillator designed by Isaacson and Jones[10] is shown in Fig. 4. It consists of a fluid-filled lucite chamber with fittings for the introduction of needles and the like from the manometer system being tested. The ends of the chamber are covered by metal membranes, one of which is coupled to an electromagnetic drive unit and the other to a strain-gauge manometer for monitoring the pressure variations produced in the chamber. A variable frequency (0.5 to 50,000 cps) electronic oscillator actuates the drive unit which translates the sine-wave oscillator current into sine-wave pressure variations in the chamber. Constant-pressure amplitude at varying frequencies is achieved by maintenance of a constant current to the drive unit, monitored by a milliammeter in the drive unit circuit. Square-wave pressure variations can also be produced by making and breaking a source of direct current to the electromagnetic driver.

Such an oscillator in use is shown in Fig. 5.

The needle of the manometer assembly undergoing test is inserted into fluid-filled lucite placed in the pressure chamber. The electromagnetic drive unit is to the left of the pressure chamber, and the strain-gauge for monitoring the generated pressure changes is on right.

The alteration in dynamic response of a strain-gauge manometer by the various components of the multipurpose manometer system shown previously is illustrated in Fig. 6.

The upper panels show the response of the water-filled gauge alone; the top trace is from the monitor gauge and the bottom from the gauge being tested. The first panel represents the square-wave response and subsequent panels show the response to sine waves of increasing frequencies. The gauge alone had a sharp resonant peak at 190 cps. Attachment of a 5-cm 20-gauge needle (0.6-mm ID) to the gauge reduced the resonant frequency to 60 cps. The polythene tube assembly had a similar effect. Combination of polythene tube and needle to complete the hydraulic system reduced the resonant frequency to 40 cps. Additional electromagnetic damping of the oscillographic galvanometer produced a reasonably satisfactory manometer system with a uniform sensitivity from 0 to 40 cps. The time lag in this manometer system of about 10 milliseconds was practically independent of the frequency in the range of from 0 to 40 cps; Fig. 6 (B). In Fig. 6(A) the top tracing in each panel is the recording from the gauge monitoring the pressure chamber and the bottom tracing is the recording from the manometer system being tested. The 20-gauge hypodermic needle was 5 cm in length and 0.056 cm in ID. The polythene tubing assembly consisted of a glass hypodermic adapter for attachment to the needle, a 26-cm length of polythene tubing (2.1-mm ID, 3.4-mm outside diameter), and a 2-

way hypodermic stopcock to permit blood sampling and connection to the manometer proper. Galvanometer damping (lower panel) consisted of the use of a galvanometer with a resonant frequency of 40 cps utilizing an external damping resistance of 70 ohms (optimal damping resistance, 250 ohms).[9]

In Fig. 6(B) note that the gauge alone, Fig. 1, has a high degree of overshoot at its resonant frequency of 190 cps. However, each hydraulic connection added to complete the system reduces this resonance point so that the complete assembly with needle attached has a resonant frequency of about 40 cps and a damping coefficient of approximately 0.2 of critical. The damping of the complete system was increased to a more optimal range by utilizing a recording galvanometer, the physical characteristics and damping of which were selected to compensate for the

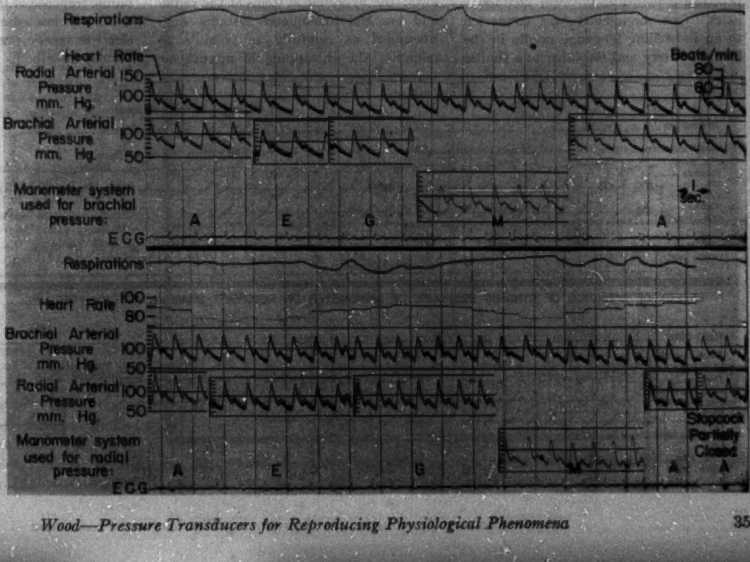

Fig. 8. Effect of variation in dynamic response of recording manometer system on contours and pressures of brachial and radial arterial pressure pulses recorded from normal subject, J. H.

overshoot of the manometer system. Note that within its range of uniform sensitivity the time lag of the complete manometer system is practically independent of frequency, a condition which minimizes distortion in the recorded contour of complex wave forms such as arterial pressure pulses.

The experimental setup for studying the minimal dynamic response characteristics needed for recording of peripheral arterial pressure pulses in man is illustrated in Fig. 2. Two strain-gauge manometer systems were used with practically identical physical characteristics. One manometer was connected to an indwelling 20-gauge needle in the brachial artery and the other to a similar needle in the radial artery. The brachial manometer was necessary to monitor the systemic blood pressure of the subject throughout the experiment so that a correction for spontaneous changes in systemic blood pressure could be made in the results obtained from the recorded radial artery pressure pulses.

The output of the radial manometer system was connected to a multiple switch arrangement so that the electric variations produced could be recorded interchangeably by four different galvanometers of widely different dynamic response. Also the mechanical damping and resonant frequency characteristics of the manometer proper could be varied by partially closing the stopcock between the manometer and the arterial needle.

The experiment was performed as follows: the hydraulic systems of the radial and brachial manometer systems were assembled as carefully as possible to minimize the entrapping of minute air bubbles. The arterial punctures were done and the needles were lightly taped in place as shown. Continuous simultaneous photographic records of radial and brachial pressure were taken while the over-all dynamic response of the radial system was varied by switching it interchangeably to the four different recording galvanometers. After several repetitions of this procedure the stopcock in the radial system was carefully turned until an appreciable difference was thought to be detected in the galvanometer trace being recorded. In part of the experiments the procedure was repeated, the dynamic response of the brachial manometer system being varied while the radial system was kept constant.

When the recordings were completed the needles were withdrawn and the dynamic response of the manometer systems used was immediately recorded by the electromagnetic-pressure oscillator previously described.

Recordings of the dynamic response of three different manometer systems are shown in Fig. 7. The top trace in each panel is a recording of the pressures, and the bottom trace is the response of the manometer system.

The top trace on each panel records pressure variations generated in the pressure oscillator chamber; see Fig. 5. The bottom trace is the response of the manometer system under test to the following pressure variations: a square-wave pressure change; sine-wave pressure variations of 0.5, 1, 5, 10, 20, 30, 40, 60, and 100 cps. The numerals toward the top of each panel are the frequencies of the sine-wave pressure variations in cps; those at the bottom, the response of the manometer under test expressed as per cent of the response at 0.5 cps: the dynamic responses of the manometer systems determined immediately after being utilized to record brachial and radial arterial pressures on normal subject J. H.; see Fig. 8.

Note that the response of the manometer systems utilized to monitor radial and brachial arterial pressure were essentially uniform out to 20 cps. The sensitivity increased thereafter to attain a peak response at about 40 cps. Partially closing the stopcock on the radial manometer system (bottom panels) decreased the range of uniform response to 10 cps with decreasing sensitivity to frequencies above this range.

The average dynamic responses of the various manometer systems used are shown in Fig. 9. The four different manometer-galvanometer systems were assembled so that one system, designated as *G*, was badly under-damped, overshooting approximately 300% at 40 cps; the second, designated as *A*, was approximately optimally damped, the response being flat to 20 cps and overshooting 20% at 40 cps; the third system *E* was overdamped, the response cutting down to 90% at 4 cps and to 60% at 20 cps; the fourth system *M* was also overdamped with a uniform response to 4 cps, cutting down to 50% at 6 cps.

Note that the upper range of uniform response for the different systems used varies from about 40 to less than 2 cps. The average figures for manometer systems designated radial systems *G*, *A*, *E*, and *M* are based on determinations carried out after the completion of the studies on each of 16 subjects. The coefficient of variation of the response at the various frequencies studied ranged from 1 to 10%.

The response of these manometer-galvanometer systems to sine-wave pressure variations when coupled interchangeably to these four different galvanometers is shown in Fig. 10. At 0.5, 1.0 and 2.0 cps the response of the four systems *A*, *E*, *G*, and *M* was uniform; however, at 10 cps the *E* system was down to 73%, the *G* was overshooting to 114% while the *M* was down to 24%; at 30 cps the *A* system response was 109%, the *E*, 56%; the *G*, 205% and the *M*, 8% of the actual pressure variation.

In Fig. 9 the top trace on each panel is a recording of the pressure variations generated in the pressure oscillator chamber; see Fig. 5. The bottom trace is the response of the manometer system under test as its output was recorded by four different galvanometers, designated *A*, *E*, *G*, and *M*, of widely different dynamic response.

Note that in each panel each of the four manometer-galvanometer systems was subjected to identical sine-wave pressure variations at frequencies ranging from 0.5 up to 100 cps. System *A* was slightly

underdamped, showing a peak sensitivity of 127% at 40 cps. System *E* was badly overdamped, showing a decrease in sensitivity from 91% at 4 cps to 61% at 40 cps. System *G* is badly underdamped having a peak response at 295% at 40 cps. System *M* exhibits an essentially uniform response out to 4 cps with a sharp cutoff in sensitivity to frequencies above this range. The response of these systems to square-wave pressure variations is shown in the lower right-hand panel. The thin vertical black lines delineate 1-second intervals.

Fig. 8 shows the effect on recorded radial and brachial artery pressure pulses when recorded by these four systems of widely different dynamic response. In the bottom panel the brachial arterial pressure recorded continuously while the dynamic response of the radial manometer system was varied by changing the position of the multiple-switching arrangement. The horizontal lines drawn through the tracings are at 50, 100 and 150 mm of mercury. Visually there is very little distortion of the pulse wave, even when the *M* system with only a 50% response at 6 cps was used.

In Fig. 8 the top panel is a continuous recording of the radial arterial pressure while the brachial arterial pressure was recorded simultaneously with the four different manometer-galvanometer systems (*A*, *E*, *G*, and *M*) of widely different dynamic response; see Fig. 9. The bottom panel is a continuous recording of the brachial arterial pressure (top) while the radial arterial pressure was recorded simultaneously with the four different manometer-galvanometer systems (*A*, *E*, *G*, *M*, and *A* with a stopcock in the hydraulic connections partially closed). The tracings of the dynamic responses of these manometer systems, exactly as used for these pressure pulse recordings, are shown in Figs. 7 and 10. The dynamic response tracings, Figs. 7 and 10, were recorded without disassembly of any portion of the manometer systems immediately after withdrawal of the needles (still connected to the manometer systems) from the radial and brachial arteries.

Note that in spite of the wide variation in the dynamic response of the manometer-galvanometer systems the contours and pressures of the pressure pulses recorded by these different systems were practically identical.

Experiments of this type were carried out on 11 normal subjects and five patients with aortic pathologic changes (aortic insufficiency, coarctation of the aorta, see Fig. 11). Only the effects obtained by varying the radial arterial manometer system will be considered, since the studies with variations in the brachial arterial manometer systems gave closely similar results. The differences in pressure recorded from the radial artery when the different systems were used could be demonstrated only by comparing all pressures to the simultaneously recorded brachial arterial pressure. When such a comparison is made, it must be realized that radial systolic pressure uniformly exceeds the systolic pressure recorded simultaneously in the brachial artery.[11]

In Fig. 11 the top panel shows the effects of variations in the manometer system on the recorded radial pulse using the simultaneously recorded brachial arterial pressure as the basis of comparison. The bottom tracing shows a similar study of the recorded brachial arterial pulse using the radial arterial pressure as the basis of comparison. The dynamic response of the four different manometer-galvanometer systems *A*, *E*, *G*, *M* is shown in Fig. 9. Note that there were no significant differences in the systolic or diastolic pressures recorded by the four manometer-galvanometer systems. However, the true contour of the peak of the pressure wave was not accurately reproduced by system *M* (the dynamic response of which was uniform out to only 4 cycles per second). Otherwise there were no evident differences in the contours of the pulses recorded by the four systems.

Average radial systolic pressures along with simultaneously recorded brachial arterial systolic pressures are shown in Table I. When manometer-galvanometer system *G* was used, the brachial minus radial systolic pressure difference

Table III. Average Effect of Variation of Dynamic Response of Manometer System on Build-up Time* of Recorded Radial Pulses

	Differences Between Build-up Times* of Radial Pulses Recorded with Manometer System A and Manometer System

Range	−0.02 to 0.01	−0.01 to 0.01	−0.03 to 0.00	−0.05 to 0.02	−0.03 to 0.01
P value of difference	<0.80	<0.70	<0.001	<0.001	<0.01

* Elapsed time from onset to systolic peak of pulse wave.

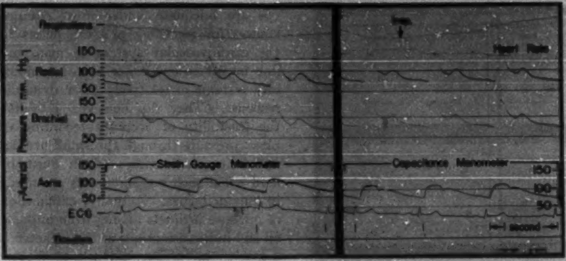

Fig. 15. Comparison of aortic pressure pulses recorded in immediate sequence from same subject by strain-gauge and by capacitance manometer-catheter systems

was −5 mm of mercury; with the *A* system this difference was −6; with the *E* system, −2; and with the *M* system, −3.5 mm of mercury. To demonstrate whether or not these small differences in pressure were significant, it was necessary to make a paired comparison of the the brachial-minus-radial pressure differences in each subject. The pressure difference recorded was used with the *A* system as the standard. Table II shows the differences in the radial minus brachial systolic pressures recorded with manometer system *A* minus the differences obtained with the other systems. These differences for manometer-galvanometer system *G* averaged 1 mm of mercury and were not statistically significant; for the *E* system, a statistically significant reduction of 4.5 mm of mercury in the radial systolic pressure was obtained, while a questionably significant reduction of 3 mm of mercury was obtained for the *M* system. The results when damping of the radial manometer was produced by partially closing the stopcock were divided into two groups A_1 and A_2 on the basis of the dynamic responses; see Fig. 9. The A_1 system included experiments in which the dynamic response of the system was more than 90% at 6 cps and less than 50% at 40 cps. The response of the A_2 group was less than 90% at 4 cps. Radial systolic pressure was not significantly affected when recorded with the A_1 system (flat to 6 cps). The A_2 system, however, with an average response of 80% at 4 cps, reduced the radial pressure on the average 17 mm of mercury.

The diastolic and mean radial pressures were not affected by any of the manometer systems used. Results similar to those stated previously were obtained from five patients with aortic pathologic changes (aortic insufficiency or coarctation; see Fig. 11).

From these studies it is concluded that, under the conditions of these experiments on resting normal and abnormal subjects with heart rates varying from 60 to 108 beats per minute, a manometer system with a uniform dynamic response out to 6 cps was adequate for accurate recording of the systolic, diastolic, and mean radial or brachial arterial pressure. Actually, practically significant errors in systolic pressure could not be demonstrated until the range of response was reduced to less than 4 cps.

An analysis has been made of the distortion of the time characteristics, i.e., the contour of the arterial pulse associated with variations in the dynamic response of the manometer system. The time delay characteristics of the various manometer-galvanometer systems were determined by recording their responses to sine-wave and square-pressure variations at a paper speed of 245 mm per second; see Fig. 12.

The recordings in Fig. 12 were taken at a paper speed of 245 mm per second to determine the time delay characteristics of a hypodermic manometer system. The top trace is a recording of the current variations in the circuit actuating the electromagnetic drive unit of the pressure oscillator; see Fig. 4. The bottom trace is a recording of the pressure variations generated in the chamber of the oscillator; see Fig. 5. The middle trace is a recording of the response of the manometer system under test, Fig. 13, to these pressure variations.

Note that there was practically no measurable time lag between the input driving current to the oscillator and the pressure variations generated therefrom. The delay in the test manometer system to sine-wave pressure variations was about 0.01 second and practically independent of the frequency.

The average time lag of the different manometer-galvanometer systems is shown in Fig. 14. The time lag of the various systems varied from 5 to 50 milliseconds. With exception of system *M* the time lag of the individual systems tended to be independent of frequency within the frequency range for which the amplitude response of the system was uniform, see Fig. 9. Table III shows differences between the pulse build-up times recorded with manometer system *A* and the other systems used. This time interval from the onset to the peak of the radial pulse wave was not significantly

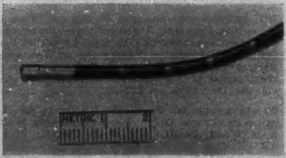

Fig. 16. Miniature variable reluctance intracardiac manometer attached to 8F Coumand cardiac catheter

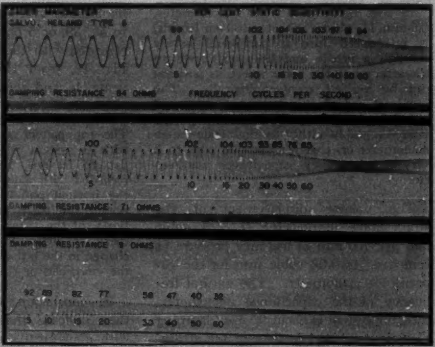
Fig. 17. Dynamic response of miniature intracardiac manometer to equal amplitude pressure variations generated by hydraulic pressure oscillator. Three damping conditions illustrated were employed to record pressure tracings shown in Fig. 18



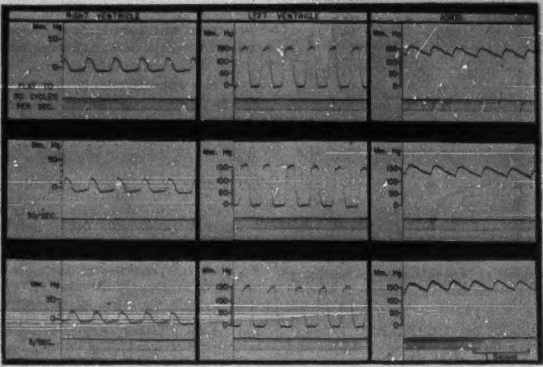


Fig. 18. Effect of rapid interchange of manometric systems with different characteristics of dynamic response on contours of pulse waves recorded from right ventricle, left ventricle, and arch of aorta in an intact dog

different when the *G*, *A*, or A_1 systems were used. A significant prolongation of this interval was detected, however, in the systems with a uniform dynamic response out to less than 4 cps.

These results, indicating that manometers with uniform dynamic sensitivity out to 6 to 10 cps are adequate to record peripheral arterial pulses, possibly may not apply to central arterial pulses or the pressure pulses generated in the chambers of the heart proper. Data have been collected which indicate, however, that such manometer systems are generally adequate for this purpose.

Fig. 13 shows a manometer assembly used for recording pressure pulses from the aorta of man. The arterial catheter, which consists of a specially prepared polyvinyl radiopaque plastic, was developed by Peterson and associates.[5]

In Fig. 13 the 1-mm outside diameter, 0.5-mm ID plastic catheter (80-cm length) is introduced into a peripheral artery through a needle and then advanced up the artery into the aorta where its position can be verified roentgenologically. The proximal end of this catheter is attached to a 2-way stopcock so it can be connected interchangeably either to the strain-gauge manometer or, through the side arm, to a very-high-frequency capacitance manometer.

The volume displacement of the strain-gauge manometer is 0.25 cubic mm per 100 mm of mercury pressure as compared to 0.02 cubic mm for the capacitance manometer. The natural frequency of the capacitance manometer-catheter system is about 90 cps (damping coefficient 0.1) while that of the strain-gauge system is 15 cps (damping coefficient 0.4).

Fig. 15 shows pressure pulses recorded interchangeably by these two manometer systems from the aorta of a normal subject. Note that there is no apparent difference in the aortic pressure pulse contours recorded by the two systems in spite of the wide divergence in dynamic response. This was a uniform finding in studies carried out in 11 normal subjects.[12]

Somewhat similar results were obtained using a miniature variable reluctance manometer, Fig. 16, small enough to be introduced directly into large vessels or the chambers of the heart.[6,7] The output of this manometer was recorded via a carrier wave amplifier by a galvanometer, the electromagnetic damping of which could be varied interchangeably so that the over-all dynamic response of the manometer system was, Fig. 17, uniform to 50, 30, or 5 cps. The pressure pulses recorded with these manometer systems, Fig. 18, from the right ventricle, left ventricle, and aorta of dogs were not appreciably different.

The top panels of Fig. 18 were recorded with a system with a dynamic response flat to 50 cps, the middle panels were recorded with a system flat to 30 cps and the bottom panels were recorded with a system flat to 5 cps. Although the sensitivity of the three systems varies slightly there is little apparent or measurable change in the pulse contours obtained from the ventricles or the aorta.

In conclusion, these results, though they indicate that manometer systems with a uniform response out to 6 to 10 cps are adequate under most circumstances for recording pressure pulses in the cardiovascular system of man, are not meant to encourage use of manometer systems of relatively poor dynamic response. They do, however, establish the feasibility of accurate recording of blood pressure through the small needles and long plastic tubes which must be used when such measurements are made in human beings. Actually, elimination of pressure artifacts arising from impacts on and induced motions of the catheter is a much more serious obstacle to obtaining high-fidelity intracardiac pressure tracings,[9] than are the dynamic response characteristics of the manometer-catheter systems commonly used.

Germanium Rectifiers for Industrial Applications

L. W. BURTON
MEMBER AIEE

MANY processes and applications in industry require d-c power which has to be obtained from an a-c source. Metallic rectifiers have served well in this field of conversion, and the operating characteristics of magnesium copper sulphide, copper oxide, and selenium are well known. A more recent development is the germanium rectifier, with different characteristics which required that new design techniques be developed. A review of these characteristics in terms of the older metallic rectifiers will be a help in understanding the design and application problems.

First will be outlined the physical construction of the germanium rectifier in comparison with the other types of metallic rectifier cells and assemblies. The selenium and copper oxide rectifiers use large rectifying areas, operating at low current densities, such as 0.3 ampere per square inch. This means the use of large cell areas or stack assemblies to provide for large power supplies. However the large area provides a simple means of dissipating the heat where it is generated. It also provides a large heat sink or thermal capacity to take care of sudden current surges or short-time overloads. Likewise, voltage surges are usually taken care of easily as long as they are not maintained over a long period. So, in selenium and copper oxide there is a rectifying device of large-area low-current density, with well-established operating characteristics and, as a consequence of the experience gained over years of successful application and operation, it is usually considered quite simple to apply and operate.

By contrast, the germanium rectifier is exceedingly small and it operates at several hundred amperes per square inch of current density. However, it is much more efficient, which results in less heat to dissipate in total but still a large amount on a unit area basis.

The germanium crystal itself is a small wafer, 0.020 to 0.030 inch thick and up to 1 inch in diameter, although most of the rectifiers for power applications use a crystal about 1/2 inch in diameter. This crystal, in turn, becomes part of a sandwich, soldered between two metal plates which become collectors. The selection of these metals is important in the electrical and thermal characteristics obtained from the cell.

In the beginning, the material selected was ferni since its expansion characteristics were somewhat similar to that of the germanium crystal. This was then soldered to a suitable cooling surface, usually of copper. The ferni, however, was a poor heat conductor in the thermal circuit. A technique has now been developed for soldering the germanium crystal directly to the copper and thus greatly improving the heat transfer characteristic of the assembly.

Various methods of cooling are used in which the cell is mounted on a suitable heat transfer device depending on the particular method to be employed. Direct forced air cooling is used, usually, for lower power applications, with liquid cooling for larger power applications. Two types of liquid cooling are generally employed. One uses a cooling agent which is a dielectric, and this is pumped or circulated directly over the cell and fin assembly. It is then passed through a liquid-to-water heat exchanger. A more recent development is direct water cooling in which the cooling fins are located directly in the water-circulating system, and the cell is mounted outside. This has a high rate of cooling and greatly simplifies servicing since each cell assembly can be removed separately.

Another consideration in cell design is that of protecting the rectifier junction from moisture and other contaminants. This was done in the earlier designs by immersing the entire cell assembly in a neutral dielectric in which a drying agent is included. A more recent procedure is to use a complete, hermetically sealed, vacuum-tight assembly with ceramic insulation, and which is welded closed. This ensures complete isolation and no possibility of injury to the cell surface. On some of the early air-cooled units the cells were protected by potting them in epon plastics. This was satisfactory, but over a long operating life, which germanium can be expected to provide, the hermetic type of seal assures that there will be no change or damage to the cell from outside contaminants.

Some of the advantages and disadvantages of the germanium rectifier are listed in the following. The means taken to overcome the disadvantages will be discussed. The advantages are:

1. High operating efficiency.
2. Very good regulation.
3. Small size.
4. Low forward resistance.
5. High reverse resistance.

The disadvantages are

1. Low thermal capacity.
2. Temperature limitations.
3. Susceptibility to current surges.
4. Susceptibility to voltage surges.

One of the outstanding advantages of the germanium rectifier is its high operating efficiency of 98% for the cells, and an over-all equipment efficiency of 94% at 95% at an operating voltage of 65 to 75 volts direct current from a 3-phase power supply. Exceptionally good regulation is obtained as a result of the low forward drop in the cell. This, however, presents difficulties in applying these rectifiers where high current outputs are to be used and where a number of cells are to be operated in parallel. It has been done successfully with as many as 24 cells operating in parallel from a single transformer secondary in a 3-phase bridge circuit. This required close forward grading and matching of the cells as well as good design practices in making bus connections and bus layouts. A small resistance value could also have been added in series with each cell, but this would have lowered the rectifier efficiency slightly. In selecting cells to operate in parallel, it is necessary to grade them at their operating current and also to be certain of similar characteristics at overload currents.

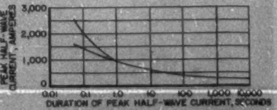

Fig. 1. Germanium cell overload current characteristics

Paper 56-78, recommended by the AIEE Metallic Rectifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 24, 1955; made available for printing December 14, 1955.

L. W. BURTON is with the General Electric Company, West Lynn, Mass.

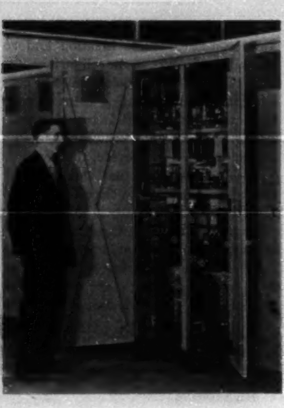

Fig. 2. Germanium rectifiers for anodizing: seven cubicles, 24 volts, 42,000 amperes

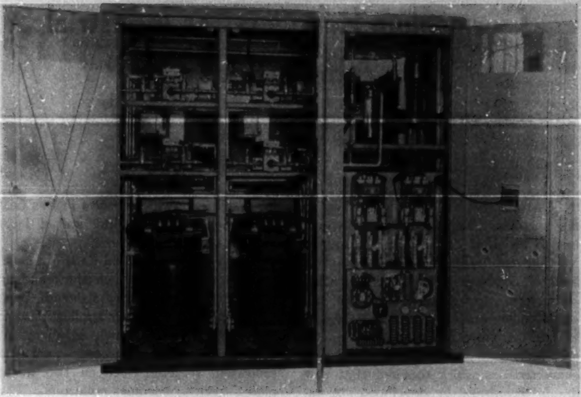

Fig. 4. Germanium rectifier single cubicle rated 60 volts, 2,000 amperes

The small size of the germanium rectifier is not only an advantage but also carries the disadvantage in terms of small thermal capacity. This shows up on overloads caused by internal faults and external short circuits.

The fault or overload current capabilities of the cell and cell assembly can be accurately calculated, and the calculations accurately verified, by precision laboratory tests. These values will vary with cell size, geometry, and materials. When the assembly is designed to give maximum heat transfer, the cell characteristics of current versus time will be similar to those shown as the top curve in Fig. 1. The cell illustrated here would have a normal continuous rating of approximately a 250-ampere peak, but could carry up to 900 amperes for 1 second, or 2,500 amperes for 0.04 second. The lower curve of the figure represents another cell assembly with less efficient heat transfer.

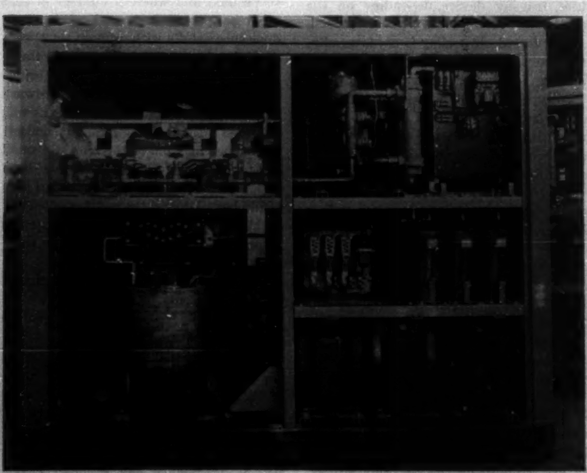

Fig. 3. Germanium rectifier single cubicle as used in Fig. 2

The limited thermal capacity of the germanium cell then brings up the problem of proper protection of the cell. It is obvious that standard fuses or circuit breakers operate too slowly to protect the cells. Also, if a circuit breaker is used with a group of cells operating in parallel, and one cell should fail (short-circuit out), the other branches would then start feeding short-circuit current to the failed cell and carry overloads that would cause other cells to fail before standard fuses or a circuit breaker could clear the fault. This could lead to the failure of as many as half the cells in the circuit.

The logical approach is then to develop a protective system for each cell, which will operate to limit fault current to a value less than that indicated as the time-current characteristics of the cell assembly (see Fig. 1). A fast-acting current-limiting fuse has been developed for this protection. It is usually placed in series with each cell, although satisfactory operation and protection have been obtained with two cells operating in parallel with one fuse. The voltage drop through the fuse is low, but it does help somewhat in balancing division of current when operating a number of cells in parallel. In circuits requiring lower current output where cells are not operated in parallel, such as a (6-1-1-*B*) 3-phase bridge, satisfactory protection can be obtained by placing the fuses in the a-c input circuit to the cells. In this case, if two or more rectifiers are operated in parallel, it is desirable to place a fast-acting fuse in the d-c output to interrupt d-c feed into an internal fault in one rectifier.

LIQUID FILLED TRANSFORMER
BUS TRANSITION AND AUXILIARY SECTION
GERMANIUM RECTIFIER SECTIONS

Fig. 5. Germanium rectifiers for gas production; 65 volts, 42,000 amperes

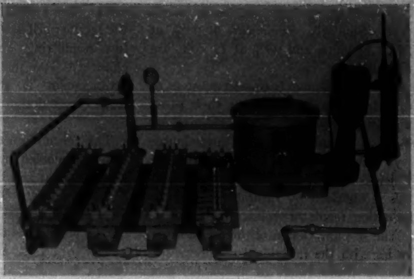

Fig. 6. Germanium rectifier cooling system

The use of a large number of fuses presents the problem of proper monitoring or signalling in case of the operation of one or more fuses. There are a number of systems which can be used, such as scanning for a voltage across each fuse at predetermined intervals, for example, once a minute. This signal can then indicate that a fuse has failed, and it can also sound an alarm.

Another characteristic of germanium which must be considered in applications is failure of the cell when transient voltages are encountered above the peak inverse voltage of the cell. The cell is destroyed when this occurs under normal operating conditions. Unhappily, it is almost impossible to apply germanium rectifiers to a system without having to contend with voltage transients. In any circuit where inductance, resistance, or stored energy in some form exists, the chances of a transient voltage are excellent. More specifically, they exist when switching inductive circuits or in energizing a system composed of inductance and resistance. The detection of a very short time-voltage transient is difficult. An electronic surge recorder or an oscilloscope with a high accelerating potential, and patience, are usually needed.

Two methods of handling this condition are used. One is to assign a voltage rating to the cell having sufficient safety factor to take care of normal surge conditions. Under normal conditions these surge voltages can run to three times the working peak voltage. The other method is to absorb these transients, since the energy content is usually low. A capacitor can normally be used to limit the magnitude of these short-time transients. If a surge counter is used, the magnitude of the capacitor may be determined by "trail and success." The capacitor size is increased until no surges above the safe value are detected. When an oscilloscope is used, the energy and magnitude of the transient can be determined, and the size of the capacitor calculated.

Another condition of operation that must be considered is the division of blocking voltage when cells are operated in series for higher voltage applications. One of the best ways of doing this is to add a small resistor across each cell. Although this decreases the efficiency slightly, it is the more acceptable method. The value of the resistance will depend upon the degree of voltage balance required and the characteristics of the cells.

The ratings of the germanium cell and the cooling system are designed to limit the cell temperature to a safe operating value. As the temperature of the cell increases, the peak inverse voltage of the cell decreases, so there is danger of cell failure if it is operated above the rated temperature rise.

From the foregoing discussion may be listed a number of conditions to be considered in designing and applying germanium rectifiers as follows:

1. The amount of overload current expected under short-circuit conditions.
2. The time the cell must withstand the overload, or the time it takes the protective device to operate.
3. The steady-state forward current.
4. The applied inverse voltage the cell must withstand.
5. The transient voltage the cell must withstand.
6. The maximum ambient temperature.

All these conditions must be considered in the designing and the use of germanium rectifiers; for example, it may be found that the surge current is more limiting than the continuous current rating, and it is necessary to operate the cell at less than its normal continuous rating. Also, there may be conditions of operation such as high ambient temperature or prolonged overloads that will increase the cell temperature above the normal operating limit.

How some of these germanium rectifiers have been applied will now be outlined. The majority of the applications now installed are for electrochemical processes requiring comparatively low voltage, high current, and high efficiency. These include applications such as the production of hydrogen, chlorine, and other gases, usually operating at 65 volts direct current. The electroplating and anodizing applications use from 12 to 48 volts direct current at high current. Power supplied to an arc reduction furnace usually required 80 volts d-c open-circuit with full-load operation at 40 to 60 volts. The tin electroplating of steel uses 15 volts, while electrocleaning uses 30 volts. All of these are desirable applications of germanium since the loads are fairly uniform with little chance of load short circuit. Efficiency is high with an over-all including all losses of 94% at

Table I. Typical Installations of Germanium Rectifiers

Application	Volts	Amperes
Electroplating	12	3,000
	12	45,000
	15	160,000
Electrolytic cleaning	30	10,000
Gas production	65	12,000
	65	16,000
	65	30,000
	65	42,000
Anodizing	24	10,000
	24	20,000
	24	40,000
	50	3,000
Arc furnace	40	4,000
	40	8,000
Total output all installations	16,000 kw	

$37^1/_2$ or 65 volts, depending on the circuit used. Similarly, efficiencies of 92% at 24 or 48 volts, and 90% at 12 volts are obtained.

The circuits have been selected so as to operate the cells at as near their rated voltage as possible. These circuits, all 3-phase, include the bridge and double wye with interphase. On applications in which control of the output is required, this is obtained by saturable reactor or induction regulator voltage control.

The size and design of the transformer varies with the individual requirements. Usually transformers of up to 300 kva have been designed and installed as part of the over-all cubicle. In some cases the cubicle includes the germanium stack assemblies, transformer, control reactor, a-c switchgear, fuse-monitoring system, and heat-exchanger type of cooling system.

For larger power requirements, these cubicles have been then connected in parallel. One such installation uses seven such cubicles to deliver 24 volts at 40,000 amperes for anodizing; see Figs. 2, 3, and 4.

Another procedure for a large block of power for a hydrogen cell line makes use of a large transformer similar to an arc furnace transformer with multiple secondaries. The rectifier banks contain only the rectifier cell assemblies and associated fuse-monitoring circuit and heat exchanger. The main advantage of this arrangement is the more economical transformer design that results; see Fig. 5.

The germanium cells in these applications are cooled by the direct, pumped liquid system and then a liquid-to-water heat exchanger. The rectifier cells are assembled in groups of 18 to 24, depending on the current required. They are then placed in a tank and completely sealed except for inlet and outlet connections for the coolant. Lead through connectors for both the alternating current and direct current are provided in the covers. The cooling system includes a reservoir and centrifugal pump which circulates the coolant at a comparatively high velocity through the trays and the heat exchanger. A drying agent is used in the coolant system together with proper temperature warning, and cutoff thermostats and flow indicator. Considerable care must be used in selecting the dielectric materials and gaskets because of the type of coolant used, since there is a tendency for the coolant to soften or attack many of the common type of insulating and gasketing material. A system layout is illustrated in Fig. 6.

With all the thought and discussion given to liquid-cooled systems, the air-cooled installations should not be forgotten. A number of 25-kw units delivering 65 volts are installed, operating in series parallel, for generating hydrogen, the reclamation of tin, and other applications. In these the air passes directly over the cooling fins. The main difficulty has been in keeping the fins clean so that proper cooling can be obtained.

These air-cooled rectifiers have given excellent service and certainly warrant consideration where water is not available for cooling, or for smaller power requirements. New fin designs now minimize the danger of clogged air passages.

A list of some of the applications now installed, or being installed, Table I, will indicate the extent to which germanium rectifiers supply d-c power to industrial installations. Their use and application are new, but no fundamental difficulties have been encountered. It seems certain that germanium rectifiers are desirable for industrial applications where power requirements are large, the output voltage comparatively low, and high operating efficiencies are desirable.

Principles of Noise Reduction in Communication Channels

L. S. SCHWARTZ
MEMBER AIEE

THE development of communication theory has led to the introduction of concepts such as integration, correlation, matched filtering, comb filtering, probability of detection, etc. Much confusion centers about the significance of these concepts because of functional equivalence and because of inadequately defined purposes in using them. Thus, it may be overlooked that integration and correlation are equivalent operations, or that matched filtering and comb filtering are techniques of integration. The purpose in using these concepts can be understood properly only within frameworks of suitable criteria of performance. For example, it is frequently assumed that the end object of a filtering technique is to improve the signal-to-noise ratio. Actually, improvement in signal-to-noise ratio is not an end in itself, but a means to an end. This end is to increase the information rate over a communication channel by reducing the probability of error.

Because of frequent confusion about the use of terms and the nature of the objectives and because of the importance of their proper understanding to rational system design, it seems desirable to discuss some basic objectives in the communications problem and to see how filtering concepts such as integration, correlation, matched filtering, etc., fall into perspective when considered within the framework of these objectives.

Communications Objectives

In communications, the transfer of a steady flow of information or a fixed amount of information from one point to another is of main concern. Communication services involving the use of teletype afford an example of a situation in which it is desired to maintain a steady flow of information. Radar is an example of a situation in which a relatively fixed amount of information is transferred, i.e., the position and/or velocity of a target at any instant.

For transfer of either a steady flow or fixed amount of information, maximum reliability is desired. In communication terms, transmission with maximum reliability is equivalent to transmission with minimum probability of error. The probability of error with which this paper is concerned is that resulting from the presence of noise in radio or radar re-

ceivers. When the concept of minimizing the probability of error is applied to digital communication systems or to search radar, it is convenient to minimize the probability of error according to either one of two, but equivalent, approaches.[1] The first approach is the criterion approach and consists in guessing whether the signal is present or not according to some criterion. In the course of guessing, the operator may make one of two kinds of errors. He may report the signal present when, in fact, it is not (called a false alarm), or he may report it as not present when, in fact, it is (called a miss). The alternative to the criterion approach is to ask: What is the probability that a signal is present, if a noise-corrupted wave form in the output of the receiver is assumed? The first approach involves the concept of likelihood directly, and the second the concept of likelihood indirectly, via inverse probability. By "likelihood" is meant the probability that the receiver will respond to signal plus noise rather than to noise alone. The optimum receiver is the one which selects the value of input signal which maximizes the likelihood.[2]

Filtering Principles in Error Minimization

In both the criterion and inverse probability methods the receiver is the operator's analyzing system, enabling him to make inferences about the input from observations on the output. The operator can use the receiver output to advantage if the receiver outputs are different when a signal is and is not present, and if he can recognize this difference. This means that he must have information about the signal, about the noise, and about his receiver. The information about the signal and the noise is usually statistical because of the random nature of noise.

In the criterion method, the problem of detection is as follows.[3] There are available N-voltage samples which are known to have come either from a distribution of signal-plus-noise voltages or from a distribution of noise voltages alone. If the signal-and-noise properties are known, the probability density function of signal and noise and that of noise alone can be specified. From knowledge of the density functions, it is possible to compute the probability that all the voltage samples came from the distribution of signal plus noise and the probability that they all came from the distribution of noise alone. The ratio of the first probability to the second is the best measure or likelihood that all samples came from the signal-plus-noise distribution. Any monotonic function of this ratio gives an equally good significance test. A constant, which the ratio must exceed to say that the samples came from the signal-plus-noise distribution, is then picked arbitrarily. This constant determines the false alarm time. If the logarithm of the ratio of the probabilities is taken, it is seen that, in the very important case of Gaussian noise at the input to the envelope detector, the measure or likelihood function indicates the following steps: to take the logarithm of the incomplete Bessel function of order zero of the voltage sample, to add these logarithms for each sample, and to require the sum to exceed a certain value (the logarithm of the constant exceeded by the ratio of probabilities), called the threshold. In other words the optimum receiver has an envelope detector with the law

$$y = \log I_0(av) \tag{1}$$

where

I_0 = the modified Bessel function of zero order
v = the amplitude of the noise voltage envelope
a = the signal-to-noise power ratio, prior to detection

(It is noted that for small values of the argument the logarithm of I_0 can be replaced by the square of its argument. For large values of the argument, the logarithm of I_0 can be replaced by the argument to the first power. Thus, the log I_0 envelope detector functions as a square law device for weak signals and as a linear device for strong signals.) Moreover, this detector is followed by an integrator which sums successive voltage samples at the output of the detector. The sum is then applied to a threshold device which, in practice, is some form of trigger circuit that operates on an all-or-none principle.

If the receiver is designed according to the foregoing criterion, it will perform in such a manner as to maximize the probability of detection for a prescribed maximum acceptable probability of false alarm given by the threshold setting. It will thus be a receiver for minimizing the probability of error.

The procedure followed in the inverse probability method achieves the same results as the criterion method. Its characteristics are now briefly described. The former method developed by Woodward[2] proceeds from the point of view of "inverse" probability since the problem is to discover the cause x which has produced a given effect y, whereas "direct" probabilities describe the effects produced by a given cause. The product law for probabilities is

$$p(x)p_x(y) = p(y)p_y(x) \tag{2}$$

where

$p(x)$ = the probability that the signal x is transmitted
$p_x(y)$ = the probability that if x is transmitted y is received
$p(y)$ = the probability that y is received
$p_y(x)$ = the probability that if y is received, x was transmitted

$p_y(x)$ is the inverse probability, and may be written as

$$p_y(x) = kp(x)p_x(y) \tag{3}$$

where $k = 1/p(y)$, a constant, since, in the reception problem, it is assumed that y is given. The quantity $p_x(y)$ is known as the likelihood function and may be replaced by a quantity $L(x)$, so that

$$p_y(x) = kp(x)L(x) \tag{4}$$

To illustrate the significance of these concepts to communications, the example of a given received signal combined with additive Gaussian noise is considered. The reception problem is to operate on the received signal-plus-noise function in such a way as to maximize the probability that the additive mixture of signal and noise originated with some particular message at the sending end. The received voltage is

$$y = u_x + n \tag{5}$$

where x denotes the message and u_x the signal voltage representing it. For a Gaussian distribution of noise,

$$L(x) = \exp[-(y-u_x)^2/2N] \tag{6}$$

where N is the mean-squared value of n, and

$$p_y(x) = kp(x)\exp\left(-\frac{1}{N_0}\int_0^T (y-u_x)^2 dt\right) \tag{7}$$

for the received signal over a time T in a receiver of bandwidth W. The samples are taken $1/2W$ second apart, and N_0 is N/W, the mean noise power per unit bandwidth. Woodward[2] has shown that maximizing $p_y(x)$ is equivalent to maximizing the likelihood function $L(x)$.

It is observed that in equation 7, $L(x)$ and, therefore, $p_y(x)$ is maximized if the integral

$$\int_0^T (y-u_x)^2 dt \tag{8}$$

is equated to zero. If the signal is constant for the duration T, the operation performed in equating the integral to zero is one of averaging the noisy wave form. If u_x is a function of time and varies over T, the likelihood function will be maximized if the function

$$q(x)=\int_0^T yu_x dt \tag{9}$$

is maximized. It may be seen from the discussion on correlation which follows in a later section that the function $q(x)$ is a measure of the crosscorrelation between y and all the possible wave forms u_x. Thus, the most probable message state is the one which yields the largest crosscorrelation. It follows that in the case of Gaussian noise the optimum receiver is a crosscorrelation device.

At first sight it may appear that the results of the criterion and inverse probability approaches are in disagreement, because it is found from the application of the former that the ideal receiver is a log I_0 detector followed by an integrator, whereas it was just found from the application of the latter that it is a crosscorrelator. Actually, the two results are not in disagreement, since the methods were applied to two different situations. In the application of the criterion approach, an envelope detector was considered but, in the application of the inverse probability approach, nothing was said about the kind of detector that was used. Now, however, the results of applying the latter approach to a case involving an envelope detector will be studied. In the foregoing attention was focused on a quantity $q(x)$ which is a measure of the crosscorrelation between y and u_x. If x is a function of time over the interval of interest $q(x)$ may be replaced by $q(\tau)$; note that u_x and $n(\tau)$, the noise voltages, are radio-frequency functions of time. It follows that $q(\tau)$, itself must also be a radio-frequency function of time, with an envelope varying comparatively slowly. By a suitable choice of ω

$$q(\tau)=Q(\tau)\cos(\omega\tau+\phi) \tag{10}$$

where ω is a high frequency with $Q(\tau)$ and ϕ varies comparatively slowly with τ. These statements merely say that $q(\tau)$ possesses fine structure and, since the inverse probability $p_y(\tau)$ is a function of $q(\tau)$, it also will exhibit fine structure which needs to be removed. It can be shown[8] that the correct procedure is to smooth $p_y(\tau)$ in such a way that the area under $p_y(\tau)$ for each interval of a radio-frequency cycle is preserved. Thus, for the smoothed distribution

$$p_y(\tau)=kp(\tau)\int_{T-\pi/\omega}^{T+\pi/\omega}\exp[Q(\tau)\cos(\omega\tau+\phi)]d\tau \tag{11}$$

The integral is $I_0(Q)$ where

I_0 = the modified Bessel function of zero order

Q = the positive envelope of q

Hence

$$p_y(\tau)=kp(\tau)I_0(Q) \tag{12}$$

The process is detection with an I_0 characteristic. If observations are taken on successive voltage samples

$$p_y(\tau)=kp(\tau)\prod_n I_0(Q_n) \tag{13}$$

This may be written alternatively as

$$p_y(\tau)=kp(\tau)\exp\left[\sum_n \log I_0(Q_n)\right] \tag{14}$$

This result shows that the most probable message state is the one which yields the largest value of the sum of sample voltages in the output of a log I_0 detector. This is the result also yielded by the criterion approach.

The implications of the foregoing results are important. It is seen that if envelope detection is specified, the optimum receiver is a log I_0 detector followed by an integrator. If not, the optimum receiver is a crosscorrelation device. In view of the fact that envelope detection is used in conventional receivers, the question arises as to whether there are times when it is preferable not to use it. The answer is yes. In envelope detection, when the signal is smaller than the noise, the noise suppresses the signal because of the nonlinearity of the process, so that the signal-to-noise ratio at the output of the envelope detector is smaller than at the input. If it is required to operate under high relative noise conditions, it is advisable, therefore, to avoid envelope detection. The alternative to envelope detection is synchronous detection which is described in some detail later in this paper. Synchronous detection will be seen to be a method of removing signal fine structure by crosscorrelation. Since crosscorrelation is a linear process, suppression of weak signals by noise does not take place.

When the question of applying crosscorrelation is considered, it will be seen that alternative ways exist for achieving it: by linear integration, by "comb" filtering, and by correlation itself. The term "matched filtering" as used here applies to integration over a single signal duration. In pulse systems, such as radar and digital communication systems, integration is over a single pulse. A matched filter may be used in conjunction with an integrator, following an envelope detector, to supplement the improvement obtained by adding successive signals.

Improving Signal-to-Noise Ratio as a Means of Minimizing the Probability of Error

Implicit in the operation of optimum receivers is the existence of a threshold device at the output of the receiver. A threshold circuit is a necessity because a receiver is, in the last analysis, a decision device. It must decide whether a signal is present or not, and it must make this decision with minimum probability of error. The decision is a yes-no operation which is implemented as to circuits by means of the threshold device. The problem of decision then resolves itself into a question of whether the output of the receiver exceeds the threshold or not. If noise alone is present, the threshold should not be exceeded, and if signal plus noise is present, the threshold should be exceeded. Since noise alone can have any amplitude with finite probability, it is evident that noise voltages will occasionally exceed the threshold and cause triggering of system output circuits, no matter what the threshold. This event is called a false alarm, and it is desired to have its probability small, a condition which is achieved by raising the threshold sufficiently. The threshold cannot be raised indefinitely, however, because then the probability of misses would become unacceptably large. Accordingly, a compromise must be reached which represents an acceptable balance between the false alarm rate and the miss rate. On the other hand, if the signal-to-noise ratio at the input of the threshold were increased, the threshold could be raised for a given miss probability, or lowered for a given false alarm probability depending on whether the signal or the noise had been increased relative to the other. In either case, the result is a reduced probability of error, the object of increasing the signal-to-noise ratio. By application of either the criterion or inverse probability approaches, it can be seen that integration or correlation, which are techniques of linear filtering, are optimum means for minimizing probability of error when the noise is Gaussian. Since the probability of error is a function (exponential) of signal-to-noise ratio, it follows that linear filtering techniques are also optimum methods of improving signal-to-noise ratio when the noise is Gaussian. For this reason, it is desira-

Vol.
Pt. 1
1956

ble to compare briefly the various techniques commonly used to improve signal-to-noise ratio and to show the relationship they bear to each other. These techniques are: matched filtering, comb filtering, linear integration, and correlation. Each of these will now be discussed.

MATCHED FILTERING

The matched filter, first considered by North[4] and then later and independently by Middleton and Van Vleck,[5] is a filter designed to achieve maximization of the signal-to-noise ratio. The figure of merit ρ, on which the filter design is based, is defined as the ratio.

$$\rho=\frac{|v(t_0)|^2}{\sigma^2} \qquad (15)$$

where

$v(t_0)$ = the value of the output signal at some specified instant $t=t_0$

σ^2 = the mean-square value of the output noise

Application of Schwartz's inequality to this ratio shows that the transfer characteristic of the filter which maximizes ρ is the complex conjugate of the spectrum function of the input signal. Such a filter has the property that its impulse response is the image of the input signal. The output of the matched filter for a rectangular pulse input is a triangular pulse the base width of which is twice the width of the input pulse. It is observed that the output of a correlation device for a rectangular pulse input is also a triangular pulse of base width equal to twice the input pulse width. Also, time-aperturing (which is convolution, an integration process) a rectangular pulse with an impulse response function which is the image of the input pulse results in a triangular output. Thus, the matched filter can be looked upon either as a correlation or an integration device. This observation will be supported by a mathematical statement in a later section dealing with correlation.

In determining the improvement accomplished by a matched filter, its performance may be compared with that of an resistance-capacitance (R/C) filter the bandwidth of which is appropriate to the signal being used. For a rectangular pulse in Gaussian noise, the maximum value of ρ is

$$\rho_{MF}=\frac{V^2\delta}{N_0} \qquad (16)$$

where

V = the amplitude of the rectangular pulse

δ = the pulse width

N_0 = the value of the noise power spectrum

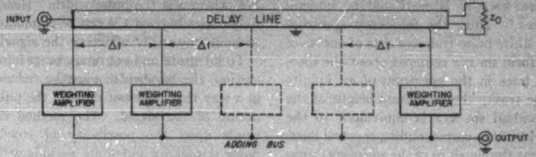

Fig. 1. Diagram of a matched filter

For an R/C filter, the output signal-to-noise power ratio is

$$\rho_{RC}=\frac{V^2\delta(1-\epsilon^{-2\pi\alpha})^2}{\alpha\pi N_0} \qquad (17)$$

where α is a factor which determines the relation that the frequency cutoff point of the R/C filter bears to the inverse of the pulse width. The other quantities have been defined previously. The improvement factor in signal-to-noise power ratio for a matched filter over an R/C filter is defined as

$$R=\frac{\rho_{MF}}{\rho_{RC}} \qquad (18)$$

$$R=\frac{\alpha\pi}{(1-\epsilon^{-2\pi\alpha})^2}. \qquad (19)$$

It is observed that the relative improvement of the matched filter over the R/C filter increases with α. This means that if the performance of the matched filter is compared with that of an R/C filter the cutoff frequency of which is appreciably larger than $1/\delta$, where δ is the pulse width for which the matched filter is designed, the performance will be better than if the comparison is made with an R/C filter of smaller relative cutoff frequency. The physical basis of the improvement is that the matched filter has a frequency transfer function which resembles the spectrum of the input signal so that, unlike a nonoptimum filter, it admits only that noise which is coincident with the spectral components of the signal or which lies between them, but not the noise which lies outside the signal spectrum.

It might be considered that a matched filter would be designed in the frequency domain since theory yields the frequency transfer function explicitly. The equivalent filter design can be achieved much more easily, however, in the time domain from knowing that the impulse response is the convolution of itself with the periodic unit impulse as scanning function. Thus the impulse response is given by

$$W(t)=\int_{-\infty}^{\infty}W(\tau)u(t-\tau)d\tau \qquad (20)$$

and

$$W(t)\backsimeq\sum_{n=0}^{N}W(n\Delta t)p(t-n\Delta t) \qquad (21)$$

where n is the total number of discrete time intervals of width Δt. In equation 21, n is summed from zero because the realizable impulse response is zero for $t<0$, and $p(t)$ is a pulse of duration Δt, approximating the impulse. Since the impulse response of the matched filter is the image of the input signal, the form of $W(t)$ is specified. The basic components of the matched filter include a tapped delay line, weighting amplifiers, and an adding bus. A block diagram of a matched filter is shown in Fig. 1.

COMB FILTERING

The comb filter, unlike the matched filter, integrates over more than one pulse. Comb-filter operation is tantamount to insertion of band-pass filters of infinitesimal width at the spectral lines of a repetitive signal. Thus, the essential frequency components of the signal are admitted by the filter whereas the noise which fills the region between spectral lines is rejected. If the band-pass filters are infinitely narrow, the filter, in effect, operates on an infinite pulse train, and the filtering is perfect. In practical applications, perfect operations is not possible, and comb filtering must be limited to a finite number of pulses. In view of this, it is necessary to consider the shape of the spectrum of a finite group of pulses as distinct from the spectrum of a succession of repetitive pulses of infinite extent.

The frequency spectrum of a signal consisting of a train of N rectangular pulses of constant width and amplitude and period T is

$$S(\omega)=\sum_{k=-\infty}^{\infty}F\left(\frac{2\pi k}{T}\right)\times\frac{\sin NT\left(\omega-\frac{2k}{T}\right)}{\frac{NT}{2}\left(\omega-\frac{2\pi k}{T}\right)} \qquad (22)$$

where $k=n/N$ is restricted to integral values.[6] Thus, the frequency spectrum of a finite pulse train consists of curves of the form $\sin x/x$ centered about the spectral lines in the spectrum of an infinite pulse train; the maximum height of the individual $\sin x/x$ is equivalent to the height of the corresponding spectral lines, so that the envelope of the entire spectrum is also of the form $\sin x/x$. As N, the number of pulses in the train, increases, the individual $\sin x/x$ curves about the spectral lines become increasingly spiked, and the spectrum approximates the line spectrum of an infinite train of pulses.

The improvement obtainable with a comb filter increases with the number of pulses on which the comb filter operates, because, as just observed, the spread of the $\sin x/x$ function about the spectral lines decreases as N increases, admitting less noise to the output of the filter. Since the transfer characteristic of an ideal (linear) integrator consists of a series of spikes at the spectral lines, the transfer characteristic of a comb filter approximates that of an ideal integrator as N increases. Because of the functional similarities between the comb filter and the linear integrator and because of the technical difficulties involved in achieving the necessary frequency stability for satisfactory operation of the comb filter, its use is not recommended.

LINEAR INTEGRATION

Integration and correlation have been widely described in the literature and have been employed to aid in the detection of periodic signals obscured by noise. The advantage of integration or correlation consists in the fact that signals reinforce upon successive additions in time, whereas noise both reinforces and cancels. It is evident that the best result is obtained when the noise has minimum correlation with itself, i.e., when it has the statistical structure of thermal noise.

Integration may be achieved by introducing the signal wave form into a number of storage elements with given delays and then summing the delayed signals. Ideally, an infinite number of pulses would be summed to obtain an infinite improvement in signal-to-noise ratio. A far from ideal example of a linear integrator is a low-pass filter which integrates by eliminating high-frequency components in the noise. Signal frequencies, however, may also be eliminated if the bandwidth of the filter is reduced beyond the point at which the signal spectrum has significant energy. For pulsed signals, as in radar, the signal spectrum has little energy at frequencies greater than $1/\delta$, where δ is the pulse width. Hence, frequencies beyond $1/\delta$ can be eliminated without materially affecting the signal.

To integrate and yet retain range information, the bandwidth must be reduced in a way that does not destroy the pulse nature of the signal. The method depends upon the possibility of storing radar signals for indefinite periods without distortion. Each repetition period is treated as a unit, and its signals are stored in such a way that they can be recovered in their correct time sequence. The combined signal, with pulses from fixed targets correctly superimposed, is given by

$$S(t)=\sum_{n=0}^{\infty} a_n s_n(t-nT) \quad 0<t<T \tag{23}$$

The change in signal-to-noise ratio may be calculated by considering a particular instant. If this instant lies within a signal pulse, the signal amplitudes will add to a sum proportional to $\sum_{0}^{\infty} a_n$. The resultant rms noise voltage on the other hand will be proportional to

$$\left(\sum_{0}^{\infty} a_n^2\right)^{1/2}$$

since the noise is uncorrelated between successive repetition periods. The improvement in signal-to-noise power ratio is therefore

$$R_I=\frac{\left(\sum_{0}^{\infty} a_n\right)^2}{\left(\sum_{0}^{\infty} a_n^2\right)} \tag{24}$$

It is clear that the signals are summed with a weighting function which, in the case of the linear integrator for radar pulses, has peaks in the repetition frequency and its harmonics. The frequency characteristic of the integrator is therefore of the comb-filter type, passing the Fourier components of the pulse train and attenuating noise at other frequencies.

CORRELATION

The subject of correlation is concerned with relations which exist between parts of the same signal, or between parts of one signal and parts of another. The former is defined by the autocorrelation function whose symbolic expression is

$$\psi_{11}(\tau)=\lim_{T\to\infty}\frac{1}{2T}\int_{-T}^{T} f_1(t)f_1(t+\tau)dt \tag{25}$$

Physically, the autocorrelation function is simply the average product obtained by comparing the given signal with itself. If the signal is completely random, different parts of the same signal will be independent of each other and, consequently, the value of the autocorrelation will be zero except for $\tau=0$, meaning that the signal is correlated with itself only. An example of a completely uncorrelated signal is thermal noise, the autocorrelation function of which is a spike at $\tau=0$. For more correlated time functions, the autocorrelation function decays to zero for increasing τ.

The crosscorrelation function differs from the autocorrelation function in that it represents the average product relationship which exists between two different time functions and is thus a measure of the amount of correlation which exists between the functions at different intervals of time. Crosscorrelation is applied when a priori information concerning the frequency of the signal is known. If there is no a priori information, no advantage is obtained over autocorrelation.

It is instructive to consider the relationship between correlation and integration. If a signal $S_i(t)$ and noise $N(t)$ are applied to a filter with an impulse response $W(t)$, the filter output $S_0(t)$ is given by the convolution integral

$$\begin{aligned}S_0(t)&=\int_0^{\infty}[S_i(\tau)+N(\tau)]W(t-\tau)d\tau\\&=\int_0^{\infty}S_i(\tau)W(t-\tau)d\tau+\int_0^{\infty}N(\tau)W(t-\tau)d\tau\end{aligned}$$

If $W(t)$ is equal to $S_i(-t)$, the condition for a matched filter, the filter output is

$$S_0(t)=\int_0^{\infty}S_i(\tau)S_i(\tau+t)d\tau+\int_0^{\infty}N(\tau)S_i(\tau+t)d\tau$$

The similarity between this latter expression and the crosscorrelation function

$$\begin{aligned}\phi_{12}(\tau)&=\lim_{T\to\infty}\frac{1}{T}\left[\int_0^{\infty}S(t)S(t+\tau)dt+\int_0^{\infty}N(t)S(t+\tau)dt\right.\\&=\lim_{T\to\infty}\frac{1}{T}\psi(\tau)\end{aligned} \tag{26}$$

obtained by crosscorrelating the stored signal $S(t)$ with the same input signal, is immediately apparent. With the exception of the averaging process, the two methods of detection are similar. The output from the filter $S_0(t)$ is a function of t, whereas $\psi(\tau)$ is a function of τ. Thus

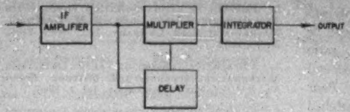

Fig. 2 (left). Block diagram of autocorrelation radar

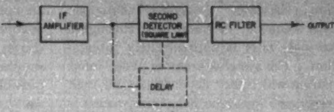

Fig. 3 (right). Block diagram of conventional radar

two types of filters may be used to obtain crosscorrelation in real time. It should be noted that the requirement that $W(t)$ be made equal to $S(-t)$ is equivalent to the requirement that the transfer characteristic of the filter be the conjugate of the Fourier transform of the signal $S_i(t)$. It will be recalled that this is precisely the condition for maximizing the peak signal-to-rms noise ratio.

If a sinusoidal function is crosscorrelated with a periodic signal possessing more than one frequency, one of which is a frequency equal to that of the sinusoidal function, the output of the correlator is a sinusoidal function of the same frequency as the correlating sinusoid. This is the same result as would be obtained if the periodic signal were passed through an infinitely narrow filter centered on the frequency of the correlating sinusoid. Since this discussion is limited to theoretically ideal correlators for which the time of integration is infinite, the correlator can be regarded as the equivalent of an infinitely narrow filter in the frequency domain. It is noted that the latter filter would have an infinite build-up time. Although correlation has its frequency domain analogue, such that the time and frequency domain viewpoints are operationally equivalent, it may be easier to build a highly stable oscillator than a correspondingly narrow bandwidth filter. If a periodic signal with harmonic components is correlated with another periodic signal possessing an infinite set of harmonic components of equal amplitude, the output of the correlator will consist of discrete frequency components representing the original signal. Thus, the ideal correlator behaves like a comb filter.

In summary the four linear techniques discussed in the foregoing are equivalent for signals in Gaussian noise in that they all maximize signal-to-noise ratio by linear integration and therefore minimize the probability of error associated with decision making.

Applications of Linear Filtering (Correlation)

Because of the importance of linear filtering techniques and because all linear techniques may be considered a form of correlation, it is worth while to look at some well-known applications to see if their noise-reducing properties can be attributed to correlation.

SYNCHRONOUS DETECTION

Conventional envelope detection utilizes only amplitude information and discards phase information, thus according to information theory, throwing away the equivalent of 3 decibels in signal-to-noise ratio. Much more serious, however, is the fact that envelope detection is a nonlinear operation which suppresses the signal if the noise exceeds the signal in amplitude. Thus, if the signal is 10 decibels below the noise at the input to the second detector, it will be 20 decibles below the noise at the output.[7] Also, because of the alteration in the statistical properties of the noise in the second detector, averaging filters are not as effective at video frequencies as they are at intermediate frequencies. From a practical standpoint, this proves to be unfortunate because the technical problems in filtering at intermediate frequencies are much more difficult than at video frequencies. Therefore, it is highly desirable to find an alternative to envelope detection.

Synchronous detection seems to be a promising alternative. Its properties are as follows. Transmitter and receiver frequencies are coherent so that the system uses phase information. Hence, it provides a 3-decibel signal-to-noise improvement over simple envelope detection. Secondly, the detection process is linear so that no suppression of the signal by the noise occurs for signals smaller than noise; since filtering operations can be conducted with equal efficiency before and after detection, practical difficulties in filtering at intermediate frequencies can be avoided.

The operation of synchronous detection is as follows. The message function $f_m(t)$ is modulated into a cosine or sine carrier at the transmitter to give

$$f_s(t)=f_m(t)\cos\omega_0 t \tag{27}$$

At the receiver the incoming signal is multiplied by a cosine or sine reference voltage of the same frequency as the carrier, the resultant voltage being

$$\begin{aligned} f_s(t)\cos\omega_0 t &= f_m(t)\cos^2\omega_0 t \\ &= \frac{f_m(t)}{2}(1+\cos 2\omega_0 t) \end{aligned} \tag{28}$$

The signal is then passed through a low-pass filter which eliminates the carrier frequency term. The output is $f_m(t)/2$. Synchronous detection is thus seen to be a linear means for removing fine structure from a received signal. To the extent that it employs multiplication with a known frequency and averaging, it resembles crosscorrelation, but it is not complete crosscorrelation because a low-pass filter is used which permits all essential harmonic components to be passed. A true correlator would permit the carrier frequency term only to be passed and thus would function as an infinitely narrow band filter.

CORRELATION IN RADAR

Pulse-Amplitude-Modulated Radar

The pulse-amplitude-modulated radar with a square-law second detector bears a striking resemblence to the autocorrelation system shown in Fig. 2 since it is really the conventional system in Fig. 3 with a delay network added. If the input signal to the circuit of Fig. 2 is a rectangularly shaped pulse, the output is a triangularly shaped pulse. If the input to the second detector in Fig. 3 is

$$f_1(t)+f_1(t+\tau) \tag{29}$$

the detector output is

$$[f_1(t)]^2+2f_1(t)f_1(t+\tau)+[f_1(t+\tau)]^2 \tag{30}$$

The R/C filter is a low-pass filter which functions approximately as an integrating device. Hence, the output of the detector is integrated and this results in

$$2\phi_{11}(0)+2\phi_{11}(\tau), \tag{31}$$

two autocorrelation functions. Because $\phi_{11}(0)$ is constant for a stationary process, the first term can be eliminated by calibration. For rectangular input pulses, $\phi_{11}(\tau)$ is a triangular function of time and thus it is seen that, with a slight modification, the pulse radar receiver can be modified to perform as an autocorrelation detector.

Continuous-Wave and Frequency-Modulated Radar

Continuous-wave doppler and frequency-modulated radars are fundamentally correlation systems since they heterodyne, i.e., multiply the received signal and a locally generated time function in the mixer. Passage of the doppler beat frequency or frequencies through a low-pass filter is approximately integration. The systems preserve phase information which they depend upon for their reading. Thus, the detection process is approximately crosscorrelation.

Conclusions

The basic objective in reducing noise in communication channels is to minimize the probability of error. The probability of error can be minimized by maximizing the likelihood ratio which, in terms of a physical operation, means improving the signal to noise. It is necessary to consider the way in which the signal-to-noise ratio is improved because there is an optimum way. In the extremely important case of Gaussian noise it can be shown that the signal-to-noise ratio should be improved by one of several possible linear filtering techniques. Four well-known techniques are: 1. matched filtering; 2. comb filtering; 3. linear integration; and 4. correlation. It is shown that all four of these techniques have equivalent properties and examples of the use of linear filtering techniques, specifically from the point of view of correlation, are given.

Application of Statistical Techniques to Electron Tubes for Use in a 4,000-Mile Transmission System

W. VAN HASTE
NONMEMBER AIEE

OVER the past several years the subject of reliability of electronic equipment has received considerable attention. Much has been written on the need for reliable systems, and the mathematical probabilities of component performance have been explored. While there have been demonstrations of achievement, it is felt that additional material of this nature will be of interest. One of the chief factors in establishing a reliable system is to assure compatibility of the operating environment and the capabilities of the active electronic device. This can best be brought about by close cooperation between the equipment and component designers.

The purposes of this paper are: 1. to give an example of the achievement of reliability in a 4,000-mile communication system and 2. to discuss some of the statistical techniques and co-operative measures used to accomplish the feat. The order of presentation relates the system objectives to tube performance requirements. The latter are in turn dependent upon the dimensions of the electrodes that comprise the tube. The control of tube parts, the resultant effect on tube characteristics and, finally, the extent to which reliable system performance has been achieved are discussed.

System Objectives

The *L-3* coaxial system was designed by the Bell Telephone Laboratories to meet telephone and television requirements in the growing demand for long-distance transmission facilities. One transmission circuit is capable of handling 1,860 telephone message channels, or one television channel and 600 telephone message channels. The transmission band is 300 kc to 8.35 megacycles and requires amplification approximately every 4 miles. In a 4,000-mile system there are thus about 1,200 amplifiers in tandem, where each amplifier employs five electron tubes as active devices.

To have a practical maintenance procedure, it is necessary to use plug-in amplifiers which, in turn imposes a requirement of complete interchangeability. To achieve this goal within the tight system limits, it is essential that the amplifiers follow a normal distribution pattern. The economical way to secure this objective is by imposing distribution requirements on the amplifier components. In the following discussion it should be remembered that, while only the electron tubes are discussed, similar considerations apply equally well to the coils, condensers, resistors, and other circuit components.

The achievement of the following broad general system objectives is dependent on the satisfactory performance of the electron tubes:

1. The resulting transmission line must be equalizable.
2. The signal should be transmitted with a sufficient degree of fidelity.
3. The system must be reliable.

Electron Tube Requirements

The relation of the basic system objectives to the electron tubes, shown in Table I, is as follows:

1. Equalization: Equalization is defined as the ability to maintain amplitude and phase of the transmitted signal at the receiving terminal within limits determined by the facility being transmitted (i.e., telephone, telegraph, telephoto, or television). This requires that the average values of transconductance of the tubes

---

Paper 56-86, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted April 20, 1955; made available for printing November 21, 1955.

W. Van Haste is with the Bell Telephone Laboratories, Inc., Allentown, Pa.

The development described in this paper was accomplished by co-operation of many people working within the following branches of the Bell System: American Telephone & Telegraph Company, Bell Telephone Laboratories, and the Western Electric Company. Special mention is made of the contribution to the preparation of this paper by B. J. Kinsburg of the Bell Telephone Laboratories.

Table I. Relation of General System Objectives to Tube Requirements

System Objectives	Tube Requirements
Line must be equalizable	transconductance must be controlled initially and with time
Fidelity of transmission must be maintained	harmonic distortion must be low
Reliability must be high	long thermionic life, minimum sudden failures

be maintained close to desired nominals, that individual values be randomly distributed around these nominals, and that the reduction of transconductance with time be gradual (less than 3 decibels (db) in 15,000 hours).

2. Fidelity: The fidelity of transmission requires at least a 40-db signal-to-noise ratio. This may be translated into the electron tube harmonic-distortion requirements. While statistical controls have been placed on these measurements, they will not be discussed in detail.

3. Reliability: The over-all reliability requirement for the 4,000-mile system is that not more than one major failure (loss of circuit for 4 hours or more) shall occur per year. Preliminary studies showed that such reliability with available components could only be achieved by providing automatic switching to a standby circuit. Assuming automatic switching, the over-all reliability objectives for electron tubes of the *L3* system are:

a. Sudden failures (glass cracks, open connections, interelectrode short circuits, etc.) shall not exceed one per 1,000 sockets per month.

b. Average thermionic life should be at least 15,000 hours.

To meet the demands of this 4,000-mile transmission system, three new electron tubes were developed by the Bell Telephone Laboratories for use in the amplifiers. These are manufactured by the Western Electric Company under code numbers *W.E. 435A*, *W.E. 436A*, and *W.E. 437A*. All of these are high-transconductance tubes, the first two being tetrodes and the last one a triode. Table II lists the important characteristics of the three tube codes under typical operating conditions.

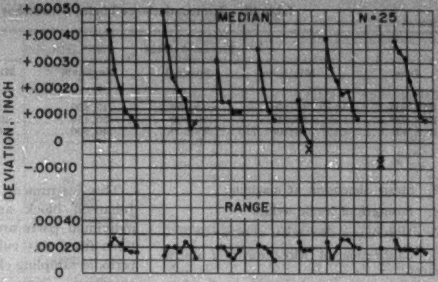

Fig. 1. Deviation of grid side rod diameter from desired nominal

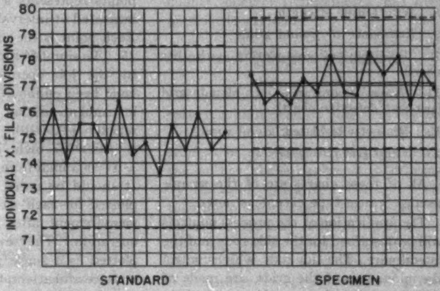

Fig. 2. Measurement of fine grid wire

Mention has been made of the need for a normal distribution of amplifiers to achieve interchangeability and also that the electron tubes used as the amplifying devices must be normally distributed in regard to some major characteristic. It is interesting to note that the 1,200 amplifiers in tandem actually work to the advantage of the manufacturers in that a normally distributed product is acceptable. In a very small system this might not always be true.

Electron Tube Manufacture

The maintenance of distributed performance of electron tubes is directly dependent on the piece parts from which the tubes are assembled. Process controls are maintained on the physical dimensions of the cathodes, grids, anodes, etc., and also on the effects of chemical processes such as cleaning, coating, heat-treating, etc. For the new tubes for the *L-3* system, virtually every part and process has statistical controls applied to it.

The control grid will be discussed in some detail since it is one of the most critical electrodes and, being unconventional, offers some novel features. A conventional grid is a self-supporting helix of lateral wire wound around two side rods. The wires are fixed in position by notching and swaging operations. To obtain the proper characteristics for the *W.E. 435A*, *W.E. 436A*, and *W.E. 437A* tubes, it is necessary to use grid lateral wire of approximately 0.0003 inch in diameter. A grid wound with such wire would not be self-supporting. The answer to the grid structure problem is a supporting frame made from two large-diameter side rods joined together by cross straps at the ends of the grid. The fine lateral wires are wound on this frame. The control charts being plotted in connection with grid manufacture are given in the following:

1. Diameter of side rods—as received.
2. Diameter of side rods—after tumbling.

Table II. Tube Characteristics

	W.E. 435A Tetrode	W.E. 436A Tetrode	W.E. 437A Triode

W.E. 437A	45,400	46,000	46,500	40,000	51,000

3. Strap dimension at machine.
4. Strength of frame welds.
5. Minor axis dimension at straps.
6. Calibration of wire-measuring instrument.
7. Diameter of bare lateral wire.
8. Wire tensile strength.
9. Resonance of wound grid.
10. Efficiency of gold-plating bath (bar chart).
11. Visual appearance of plated grid (per-cent defective chart).
12. Diameter of plated lateral wire.
13. Final grid resonance.

All of these charts are of the sample average–range type except as noted.

The application of the process controls will be described for the side rods and the lateral wire. The side rods, which control the minor axis of the grids, are made of molybdenum and are required to be held to a tolerance of ±0.0001 inch on diameters in the order of 0.040 inch. The parts are purchased oversize and are literally tumbled down to the proper size in an abrasive solution. An analysis of variance demonstrated that the measuring method is of great importance in obtaining results of the proper significance. Use of barrel micrometers and dial-indicating gauges were found inadequate and side-rod diameter measurements are now made on a supermicrometer.

This instrument is calibrated with a Johansen block and measurements of individual parts are recorded as deviations from this value. Fig. 1 shows a periodic sampling chart for the tumbling operation. Each group of connected points represents a lot of tumbled rods measured at intervals during the process. Each point is the median of a sample of 25. To simplify the handling of numbers by the job operators, negative values have been eliminated by calibrating the instrument so that a nominal part will register +0.00010. The process average is +0.00007 inch, indicating a product −0.00003 inch from the desired nominal. It should be noted that the final point plotted for each set of rods represents a measurement after a chemical cleaning operation. The seventh lot of rods is plotted as a single point, illustrating an unsuccessful attempt to eliminate periodic measurements. Horizontal lines on this chart represent objective working limits and not process control limits.

Another intricate problem of measurement is encountered with the grid lateral wire which is nominally 0.00029-inch ±0.00001-inch-diameter tungsten (etched to the proper diameter). Complication of this measurement is introduced by requiring an accurate figure on the thickness of the gold that is plated on the wire. The precision demanded for this work taxes the available instruments as well as the personnel operating them. Variations between operators and differences between successive readings taken at the same point on the wire are often large enough to nullify an entire set of data. The solution to this measurement problem has been to disregard all individual readings and to base the results on statistical samples. A standard wire has been selected and its diameter ascertained by averaging a series of measurements made on an electron microscope. Fig. 2 illustrates the method of measuring a new specimen. The readings are taken on a 625-power monocular microscope equipped with a Filar eyepiece. A series of measurements is made on the standard wire and another series on the specimen. The difference between process averages, expressed as "Filar divisions," is converted into microinches and is added to or subtracted from the accepted diameter of the standard to give the diameter of the specimen. Acceptance or rejection of wire is on the basis of meeting limits of 0.000290 inch ±0.000010 inch for the diameter.

Electron Tube Performance

A steady flow of normally distributed tube parts on the manufacturing line has permitted production of tubes that satisfy the design objectives. Since the characteristic of particular importance to the transmission system is transconductance, this parameter is required to meet strict limits in regard to the process average. The limits which are being met are given in Table III.

The results achieved in control of transconductance are illustrated in Fig. 3. This is an actual production control chart for the *W.E. 435A* tube.

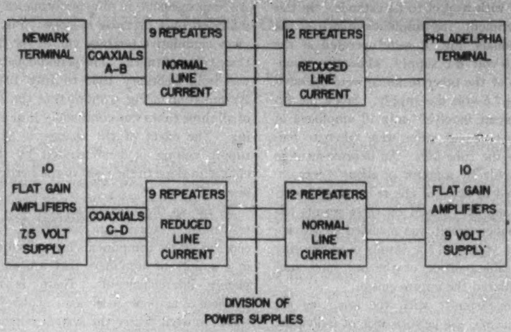

Fig. 5. Line experiments on the Newark-Philadelphia L3 system

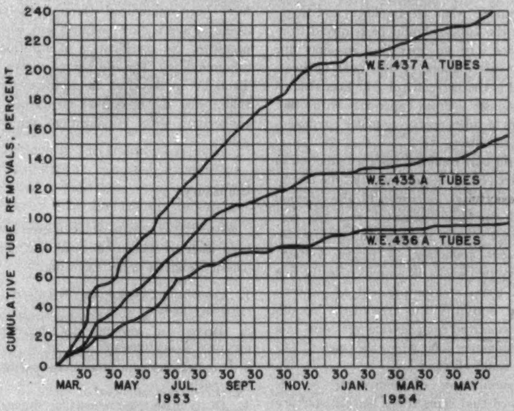

Fig. 6. Cumulative tube removals from the Newark-Philadelphia L3 system

Several sets of limits are indicated on the chart where N is the nominal (desired objective) value and A is half of the permissible range for individuals:

1. The test specification limits applicable to individual tubes: S limits $=N\pm A$.
2. The C limits for controlling the sample average X': C limits $=N\pm 0.5\ A$.
3. The D limits for controlling the process average X'': D limits $=N\pm 0.1\ A$.
4. The E limit or control limit for range R: E limit $=1.48\ A$.

To satisfy the system requirements, random shipment of tubes is permitted only if the following eligibility requirements are met:

1. X' falls within the C limits.
2. X' falls outside the C limits but the six preceding consecutive averages fall within the C limits.
3. X' and the six preceding consecutive averages do not fall outside the same D limit. (This in effect controls X''.)
4. The range R falls within the E limit, or falls outside the E limit but the six preceding consecutive ranges fall within the E limit.

Loss of eligibility requires shipment of product in small groups to a forced symmetrical distribution. The effectiveness of the control measures is demonstrated by the fact that, for all but a short period of time, eligibility for random shipment of tubes has been maintained.

When it is desirable to control more than one characteristic of the product, the more important one is subject to control with restrictions on shipment. The other characteristics are monitored by a records method where plotting control charts is mandatory, but shipment of the product is not contingent on the evidence of the charts. However, the producer is responsible for bringing the process under control. A detailed discussion of these quality control requirements has been published previously.[1]

Table IV. Reliability of Tubes in Entire System

Characteristic	Objective	Experience
Sudden failure rate	<1 per 1,000 sockets per month	approximately 2 per 1,000
Tube life, hours	15,000 average	
W.E. 435 A		18,000
W.E. 436 A		>30,000
W.E. 437 A		10,000

Tube and System Performance

The life of electron tubes is, figuratively speaking, influenced by both heredity and environment. The heredity of the electron tubes depends on the processes at the factory; the environment is furnished by the field operating conditions. The tube life problem cannot be solved at the factory alone but requires co-operation with the system designer and extensive analysis of performance data in the field. Furthermore, co-operation should be continuous and should start in the design stage.

The life and reliability problems of the *L-3* system are co-ordinated by a committee comprising representatives of tube design, tube manufacture, circuit design, circuit manufacture, and system operation (the customer). The function of the committee is to act as a planning board and to review and disseminate information. The detailed work is done in smaller subcommittees.

A flow diagram showing the approach to the life problems is given in Fig. 4. The left half of the chart shows the functions of the tube designers and manufacturers while the right half lists the system design and operation effort. Solid arrows indicate the flow of product, and dotted arrows the flow of information. It will be noted that, while tubes were in the development stage, models were submitted for laboratory amplifier testing. Later, when full production had been established, the system was used as a life rack and correlation studies were made with data obtained on life samples at the tube factory.

Tube identification has been maintained by designating weekly production lots and by numbering individual tubes. Weekly lots are kept as homogeneous as possible in regard to materials and processes. The culmination of this segregation program is the certification of product by these weekly production lots. To assure a temporary field life objective of at least 8,000 hours, tubes are accepted for system use if life samples successfully pass a 2,000-hour test. Where the sample fails to meet the 2,000-hour criterion, the lot is withheld from system use. The factory life sample (five tubes from lots averaging about 125 tubes) is augmented by data from the field correlation studies mentioned in the foregoings. In other words, a portion of the system is used as a life rack to provide data for certification of the tubes intended for general system use.

The initial installation of equipment was in a field trial between Newark and Philadelphia. The experience of this trial in which the entire circuit was used as a life rack (handling about 500 tubes) showed that the life picture was very uneven and was related to tube lots. This furnished some valuable clues as to where to look for sources of trouble and emphasized the benefits of the committee operation.

During this phase of operation two designed experiments were initiated to ascertain the effects on tube life of different operating conditions. The experiments were run simultaneously and are shown schematically in Fig. 5. The system comprises two sets of coaxial cables, designated *A-B* and *C-D* in Fig. 5, and is divided so that approximately equal sections are powered from each of the two terminals (Newark and Philadelphia). In two sections the line current was reduced to 95 per cent of the normal operating value and was left at normal in the other two sections. The effect was operation of half of the tubes at reduced heater power and the remainder at normal heater power. The experiment was balanced to permit statistical treatment of the data from coaxials and power sections. While about 15-per-cent improvement in average tube life was noted at the reduced power, this was not considered sufficient to warrant a change and the system continues to operate at the original power level.

The second of the designed experiments evaluated tube life in relation to d-c feedback. In the amplifier the control grid of each tube was returned to a +9-volt potential rather than to ground, and about 10 volts were developed across each cathode resistor. As a result of this combination bias, the net bias of each control grid is in the order of −1 volt with respect to its cathode. In this experiment, the amplifiers at one of the terminals, Fig. 5, were operated at the +9.0-volt d-c supply, while the amplifiers at the other terminal were operated at +7.5-volt d-c supply. Since the experiment involved only 10 amplifiers at each terminal, steps were taken to balance the tube lots. An improvement in tube life by a factor of about 3 was observed in favor of the reduced grid voltage supply. Based on these results the amplifier circuit was modified to provide +7.5 volts and the results of monitoring a sizable portion of the line have substantiated the improvement.

Concurrently with the foregoing experiments, the performance of individual tubes was analyzed. This dealt with the measurements being used in the field to determine when an amplifier, and therefore the tubes, should be removed from service. In an operating amplifier the only tube parameter which can be measured is the net control grid bias defined previously. From experinece with other types of tubes operating under combined-bias conditions, it is known that the change in grid bias resulting from a reduction in heater voltage correlates with tube thermionic activity. Accordingly, the criterion used for tube removal was the percentage change in bias caused by a 10-per-cent reduction of heater voltage. Every two weeks all amplifiers in the line were tested and the per-cent ΔE_c (thermionic activity) was recorded. Amplifiers removed from service were sent to a maintenance point where the per-cent ΔE_c was again checked.

Examination of individual records showed that some tubes had satisfactory activity readings in the field but failed to meet maintenance limits. On-the-spot investigation and correlation studies disclosed that this discrepancy was only apparent and was caused by differences in measuring equipment and supply voltages. A graded pattern of limits has been established to compensate for these differences.

System Reliability

A simple and effective way of showing the field life performance of tubes is a plot of cumulative removals against calender time. In a stable system, i.e,. when the replacement tubes come from essentially the same universe as the tubes already in service and the environment is constant, the plot will be a straight line. An improvement in life performance is indicated by a decrease in slope. Fig. 6 gives cumulative removal curves for the three types of tubes. The period covered was from February 1953 to July 1954. Examination of Fig. 6 shows that the life of all three tubes was continually improving. The effect of the change in grid supply voltage is demonstrated by the change in slope to the right of the vertical line.

As far as the broader aspects of the transmission system are concerned, the controls on the components have resulted in a supply of amplifiers that are completely interchangeable. There is no problem of amplifier selection. Table IV shows to what degree the system reliability objectives have been met in regard to tube performance. The sudden failures have been minimized through factory assembly and testing measures and, where necessary, by specification of additional requirements. The life figures shown in Table IV are based on end-of-life criteria that insure the objectives mentioned in connection with equalization requirements.

Summary

A variety of statistical techniques have been used to achieve the results to date. These are given in the following:

1. Probability theory for derivation of reliability limits.
2. Analysis of variance for measuring accuracy of instruments.
3. Control charts for production control of tube parts.
4. Distribution requirements for shipment of product.
5. Correlation studies for field and maintenance test limits.
6. Designed experiments for field life evaluation.

While there is more to be done to improve some of the reliability factors, it is felt that the results achieved could not have been accomplished without the use of these statistical tools. In addition, the effective operation of the co-ordinating committee is credited with a share in this achievement.

Delay Distortion Correction

W. D. CANNON
FELLOW AIEE

IN FACSIMILE and data transmission systems the signals are largely transient in nature and are usually in the form of a modulated wave for transmission purposes. The modulating signals may be in the form of isolated pulses, periodic waves, or various other wave shapes depending upon the nature of the communication device or system. Modulated pulse envelopes are thus present in the transmission medium in various combinations of amplitude, duration, and relative positions. It is therefore necessary to consider the transient response characteristics of transmission systems and associated networks as well as their steady-state properties.

A fundamental problem in the transmission of modulated pulses is the resulting distortion arising from imperfections in the transmission medium and circuitry in the form of amplitude and delay variations with respect to frequency and bandwidth limitations. In transmission the pulse envelopes may be broadened, displaced from their true positions, or destroyed beyond recognition. Amplitude distortion usually can be corrected by simple means. Delay distortion correction, on the other hand, involves relatively more complicated measuring techniques and compensating networks.

It is usual to provide correction for envelope delay distortion and ignore other forms of delay distortion. An instrument has been developed for the measurement of envelope delay characteristics as well as amplitude characteristics.[1] By the use of this instrument these characteristics may be displayed continuously by a cathode-ray oscilloscope. Thus each alteration in the characteristic by the insertion of corrective measures is immediately displayed so that the process of corrective insertion and observation is continued until the characteristic is within a prescribed tolerance. The usual passive recurrent-structure corrective network is impractical for the rapid insertion of new delay values in small steps for observation. This paper includes consideration of distortion properties and the development of a more practical means of correction, particularly for use in conjunction with the envelope delay measuring instrument.

Pulse Transmission Characteristics

Since facsimile and data signals contain wave shapes in the form of pulses and depend upon the relative phases of the component frequencies as well as upon relative amplitudes for preservation of wave shape, it is necessary to consider both amplitude and phase responses. It is usual to predict the transient response of a circuit or network from the steady-state amplitude and phase responses. These responses may be expressed in closed form by relations such as a Fourier integral equation:

$$A(t)=\frac{1}{2}S_0+\frac{1}{\pi}\int_0^\infty \frac{S(\omega)}{\omega}\sin\,[\omega t+\varphi(\omega)]\,d\omega \tag{1}$$

where $A(t)$ is response due to unit step function, S_0 is response after the transient has disappeared, $S(\omega)$ is amplitude response as a function of ω, and $\varphi(\omega)$ is phase response as a function of ω.

The phase response $\varphi(\omega)$ can in general be expressed as the sum of three components. The first is the minimum phase component which has a definite relationship to the amplitude response and is therefore of particular interest with respect to limited bandwidths. In minimum phase systems equation 1 can be expressed in terms of either the amplitude response $S(\omega)$ or the phase response $\varphi(\omega)$. The second is a linear component which represents a constant transmission time for all frequencies. The third component is independent of the amplitude response and hence may be used for application in networks for correcting the phase response to be a linear characteristic with respect to frequency. In this case $S(\omega)$ is a constant and transient response $A(t)$ is dependent upon the phase response $\varphi(\omega)$. These components give rise to different forms of phase distortion. The properties of some of these forms will be considered briefly.

The amplitude response $S(\omega)$ and the phase response $\varphi(\omega)$ are usually considered in terms of the steady-state parameters α, attenuation constant; and β, the phase shift constant so that the propagation constant is $\alpha+j\beta$. The phase-related parameters that are associated with facsimile signal distortion may be expressed in terms β/ω which is the phase delay and $d\beta/d\omega$ which is the envelope or group delay. In addition, higher order derivatives are sometimes of importance particularly when aperiodic waves are involved.[2, 3]

In the transmission of periodic waves or pulse trains such as are generated when a number of equally spaced lines are scanned, it is convenient to express such waves in the form of a Fourier series

$$\begin{aligned}E(t)=\frac{a_0}{2}+a_1\sin pt+a_2\sin 2pt+\\ \ldots a_n\sin npt+b_1\cos pt+\\ b_2\cos 2pt+\ldots b_n\cos npt\end{aligned} \tag{2}$$

where the parameters may be determined by the usual Fourier methods. If used to modulate a carrier, double side band, the resulting transmission is

$$V_1=A_1\cos\omega_c t[1+ME(t)] \tag{3}$$

where $\omega_c/2\pi$ is carrier frequency, A_1 is carrier amplitude, and M is modulation factor. If this wave V_1 is transmitted through a medium having a linear phase shift as shown in Fig. 1, curve 1, each sinusoidal component of $E(t)$ will be received in the form

$$\begin{aligned}V_2=A\cos\omega_c(t+k)+\frac{Ab_nM}{2}\cos(\omega_c+\\ np)(t+k)+\frac{Ab_nM}{2}\cos(\omega_c-np)(t+k)\end{aligned} \tag{4}$$

Hence, the carrier and two side-band frequencies will be delayed in transmission by the factor $\beta/\omega=d\beta/d\omega=k$ so that all components of $E(t)$ will be delayed equally and the wave shape will be preserved in transmission. If the medium has a linear phase shift which does not intercept the β-axis at 0 or $m\pi$, where m is an integer, as shown by curve 2, Fig. 1, a form of distortion occurs known as linear phase intercept distortion. Here the phase delay $\beta/\omega=k+\beta_1/\omega$ and the envelope delay $d\beta/d\omega=k$ are not equal. In this case each sinusoidal component of $E(t)$ will be received in the form

$$V_2 = A\cos[\omega_c(t+k)+\beta_1] + \frac{Ab_nM}{2}\times \cos[(\omega_c+np)(t+k)+\beta_1] + \frac{Ab_nM}{2}\cos[(\omega_c-np)(t+k)+\beta_1] \quad (5)$$

which in envelope form is

$$V_2 = A\cos[\omega_c(t+k)+\beta_1][1+Mb_n\times \cos np(t+k)] \quad (6)$$

Hence the carrier is delayed by the phase delay and the envelope is delayed by the envelope delay of the medium.

The question often arises as to whether linear phase intercept distortion is of importance in facsimile and data transmission systems where information may be present in the form of modulated pulses, whereas unmodulated signals such as the $E(t)$ waves of equation 1 when transmitted directly over a circuit could be distorted beyond recognition unless the intercept is 0 or $m\pi$. From the foregoing it can be seen that in the case of modulated signals the envelope is not distorted in transmission but that the carrier is shifted in phase under the envelope. Hence this form of distortion may be neglected, unless some use is to be made of the individual cycles of the carrier, in which case correction need be made only for envelope delay. However, the peaks of the carrier cycles are often used for marking or sampling rather than the recovered envelope. In this case the necessity for intercept correction is minimized if the carrier frequency is high relative to the modulation frequency since the constant carrier phase shift angle β_1 will then represent a small time displacement relative to the signal interval. This relationship may be effected, if it should not naturally exist in the system, by frequency multiplication at the receiver which will multiply the carrier frequency ω_c and leave the modulation frequency unchanged.

For a medium in which the phase shift is not linear, a number of different types of distortion arise depending upon the phase characteristic. A few types of phase characteristics are discussed in the following. Since a delay common to all signal frequencies produces no wave-form distortion, that part of the phase shift which is linear with frequency may be ignored for present purposes. The results of nonlinear distortion may for convenience be expressed with respect to the average value of the phase shifts β_4 and β_5 of the side frequencies of a component of $E(t)$, Fig 2. The received modulated component then will be

$$V_3 = A\cos(\omega_c t+\beta_2) + \frac{Ab_nM}{2}\times \cos[(\omega_c+np)t+\beta_3] + \frac{Ab_nM}{2}\cos[(\omega_c-np)t-\beta_3] \quad (7)$$

$$= A\cos\omega_c t[\cos\beta_2 + b_nM\cos(npt+\beta_3)] - A\sin\omega_c t\sin\beta_2 \quad (8)$$

where

$$\beta_2 = \frac{\beta_5-\beta_4}{2} \text{ and } \beta_3 = \frac{\beta_4+\beta_5}{2} \quad (9)$$

which in envelope form becomes

$$V_3 = A\sqrt{1+2b_nM\cos\beta_2\cos(npt+\beta_3)+b_n^2M^2\cos^2(npt+\beta_3)}\times \cos(\omega_c t+\theta) \quad (10)$$

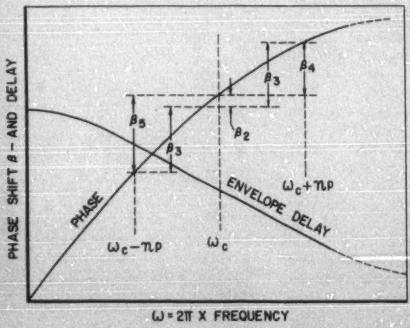

Fig. 2 (left). Nonlinear phase shift characteristics

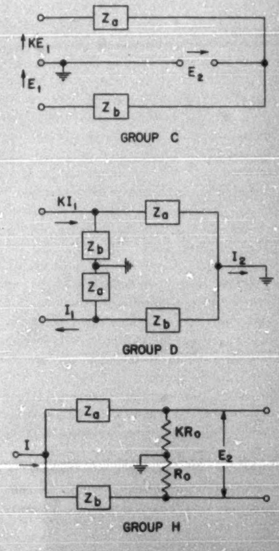

Fig. 4 (right). Typical network configurations for groups C, D, and H

Vol. 7
Pt. 1
1956

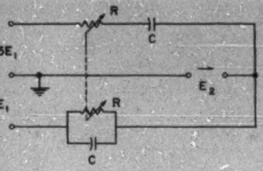

Fig. 5 (left). Phase shifting K=5 network applied to group C

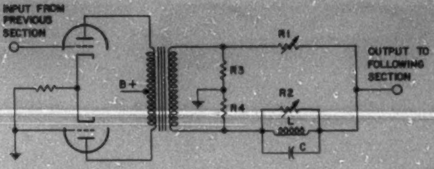

Fig. 6 (right). Active corrective network section

where

$$\theta=\tan^{-1}\frac{-\sin\beta_2}{\cos\beta_2+b_nM\cos(npt+\beta_2)} \qquad (11)$$

It will be observed that there is envelope distortion due to the presence of the cos β_2 term and some degree of phase modulation due to the variation of θ with npt. If the phase shift $\beta_2=\pi/2$ the envelope of equation 10 becomes

$$A\sqrt{1+b_n^2M^2\cos^2(npt+\beta_2)} \qquad (12)$$

$$=A\left[1+\frac{b_n^2M^2}{2}\cos^2(npt+\beta_2)-\frac{b_n^4M^4}{8}\cos^4(npt+\beta_2)\right]\ldots$$

The first term of this series becomes

$$A\left[1+\frac{b_n^2M^2}{4}+\frac{b_n^2M^2}{4}\cos 2(npt+\beta_2)\right] \qquad (13)$$

Hence the original modulation is destroyed and a double-frequency term of the modulation as well as decreasing amounts of higher even order terms arise. If phase shift β_2 is 0 or $m\pi$ the envelope is

$$A\sqrt{1\pm 2b_nM\cos(npt+\beta_2)+b_n^2M^2\cos^2(npt+\beta_2)} \qquad (14)$$

$$=A[1\pm b_nM\cos(npt+\beta_2)]$$

whence there is no envelope distortion but merely a reversal of sign for even values of m which is of no consequence. The result for double side-band transmission is thus analogous to intercept distortion with respect to the intercept points on the vertical axis which has been modulated up to carrier position and has the same relation in phase shift of $\beta_2=0$ or $m\pi$.

If the carrier is located at a point of odd symmetry on the phase characteristic as shown in Fig. 3, β_2 will be zero and from equation 8 the received component will be

$$V_2=A\cos\omega_c t[1+b_nM\cos(npt+\beta_2)] \qquad (15)$$

and no intercept type of distortion occurs. However, the different components of $E(t)$ will not be delayed equally and some envelope distortion will remain. It is thus desirable in facsimile double sideband transmission practice to locate the carrier at a point of even symmetry on the delay characteristic in order to minimize signal distortion.

In the foregoing it has been assumed that the amplitude characteristic is constant throughout the useful frequency range. If both amplitude and delay characteristics are not constant with frequency other forms of distortion take place. One particular type takes place in the form of echoes which in recorded form results in ghosts. An echo results if the amplitude has a cosine variation and the phase characteristic has a corresponding sine variation, or conversely, with respect to frequency.[4,5] In this case the spacing of the echo from the original pulse depends upon the spacing of these sinusoidal variations with respect to frequency.

However, it is usually sufficient to make correction only for envelope delay distortion in addition to the usual amplitude correction. It is not necessary to consider phase shift directly as such. When satisfactory correction has been made for envelope delay distortion, it usually will be found that phase delay distortion is within tolerable limits particularly if a sufficient number of carrier cycles exist under the modulation envelope. Accordingly, networks have been considered here mainly for the correction of envelope delay distortion.

Corrective Network Characteristics

For the compensation of delay distortion in carrier "vehicle" bands and associated equipment, types of corrective networks which may be readily designed and individually adjusted to meet the conditions of a particular application are required. For use with the delay measuring instrument, they must be readily adjustable either continuously or in small steps to compensate for a deficiency at any point in the useful frequency range. Such networks, generally designated as all-pass are usually designed to have an amplitude characteristic which is essentially independent of frequency throughout the useful frequency range These networks may be passive or active. Active networks have a property not possessed by passive networks that the delay characteristic can be readily varied over a wide range, whereas passive networks that permit the delay characteristic to be varied over the necessary range become impracticably complicated. Also, it is the property of some types of active networks that in addition to the adjustable delay feature, the amplitude characteristics may be varied over a limited range to compensate circuit amplitude distortion or amplitude distortion introduced by other networks.

The passive networks usually considered for distortion correction are the constant-resistance recurrent structures designed to match the line impedance.[6] Active networks may be designed for various conditions of input and output terminating impedances and methods of injecting the input and extracting the output. A number of these are given in Table I.

It can be readily shown that the transfer function of a delay network having an attenuation or gain which is constant with frequency can be expressed in the form

$$N\frac{A\pm jB}{A\mp jB}=N\underline{/\beta} \qquad (16)$$

or other equivalent expressions, where B is $2\tan^{-1}\pm B/A$ and N is a constant.

A and B are functions of ω and the network parameters. For the present purposes the constant N may be neglected.

In general the groups listed in the table can be realized by a number of network configurations. A typical network configuration for groups C, D, and H is shown in Fig. 4 for which the output to input transfer ratio is of the form

$$\frac{E_2}{E_1}=\frac{KZ_b-Z_a}{Z_a+Z_b} \qquad (17)$$

where Z_a and Z_b are functions of ω and the network parameters, and K is a proportionality factor. The proportionality factor K may be real or complex. However, only real numbers will be considered here.

Under certain prescribed relations among the parameters, the factor K may take on integer values. If $K=1$ equation 17 is directly in the form of equation 16. The result is the well-known delay network in which the conditions are satisfied by a resistance for Z_a and a reactance for Z_b so that

Fig. 7. Passive corrective network

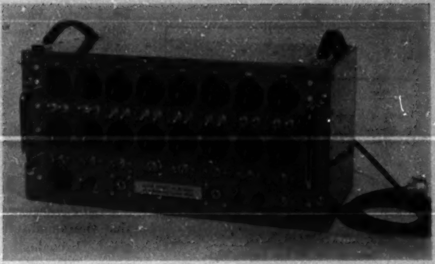

Fig. 8. Active corrective network

$$\frac{E_2}{E_1}=\frac{jX-R}{jX+R} \tag{18}$$

and

$$\beta=2\tan^{-1}\frac{X}{R} \tag{19}$$

If $K=3$ the conditions can be satisfied by the use of a resistance for Z_a and a resistance and reactance in parallel for Z_b so that

$$\frac{E_2}{E_1}=\frac{2jX-R}{2jX+R} \tag{20}$$

and

$$\beta=2\tan^{-1}\frac{2X}{R} \tag{21}$$

For $K=5$, the conditions can be satisfied by impedance functions for Z_a and Z_b such as

$$Z_a=R_1+jX \text{ and } Z_b=\frac{jMR_2X}{R_2+jMX} \tag{22}$$

where M is a constant.

However, a very useful form occurs when $M=1$ and $R_1=R_2=R$ in which the output-input transfer ratio is

$$\frac{E_2}{E_1}=\frac{3jRX-(R^2-X^2)}{3jRX+(R^2-X^2)} \tag{23}$$

and

$$\beta=2\tan^{-1}\frac{3RX}{R^2-X^2} \tag{24}$$

The $K=3$ and $K=5$ series of networks are particularly useful in phase shifting and delay networks. A very simple phase shifting network applied to group C is shown in Fig. 5 in which, from equation 24,

$$\beta=2\tan^{-1}\frac{3\omega RC}{\omega^2R^2C^2-1} \tag{25}$$

A range for fixed values of ω and C from approximately 0 to 360 degrees is obtained with constant amplitude throughout this range merely by simultaneously varying the two equal resistors R.

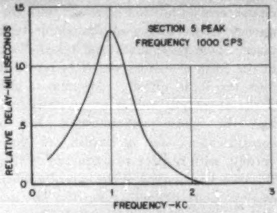

Fig. 9. Envelope delay characteristic of a passive network section

The $K=3$ series has been selected for delay distortion correction where variable delay properties are essential. The schematic arrangement of a section is shown in Fig. 6 where the resistor R_1 is used for Z_a and the parallel arrangement of resistor R_2, inductor L and capacitor C is used for Z_b. The $K=3$ factor is obtained by the divider R_3 and R_4 such that $R_3/R_4=3$. The delay characteristic is varied by R_1 and R_2. If these resistors are maintained equal, the delay characteristic will be dependent upon their common value while the amplitude characteristic will remain constant for all settings and from equation 21 β will be

$$\beta=2\tan^{-1}\frac{2\frac{\omega}{\omega_0}\sqrt{L/C}}{\left[1-\left(\frac{\omega}{\omega_0}\right)^2\right]R} \tag{26}$$

If, in addition, it is desirable to produce a variable amplitude characteristic, this can be accomplished by offsetting resistor R_2 with respect to resistor R_1. In this case the output-input transfer ratio and delay can readily be shown to be

$$\frac{E_2}{E_1}=\frac{jX(3R_2-R_1)-R_1R_2}{jX(R_2+R_1)+R_1R_2} \tag{27}$$

$$\beta=\tan^{-1}\frac{X}{\frac{R_1R_2}{3R_2-R_1}}+\tan^{-1}\frac{X}{\frac{R_1R_2}{R_1+R_2}} \tag{28}$$

where

$$X=\frac{\frac{\omega}{\omega_0}\sqrt{L/C}}{1-\left(\frac{\omega}{\omega_0}\right)^2} \tag{29}$$

If R_2 is larger than R_1 the amplitude characteristic, from equation 27, will be peaked upward in the vicinity of the resonant frequency ω_0. If R_2 is smaller than R_1 it will be peaked downward. Thus with these networks it is possible to adjust the delay characteristic over a wide range and the amplitude characteristic over a somewhat restricted range essentially independent of each other merely by adjusting two resistors and maintaining a proper relationship between them in accordance with equations 27 and 28. Practically, it is usually necessary to change only R_2 from equality with R_1 to change from a flat amplitude characteristic to a peaked characteristic in the vicinity of ω_0. This is not possible with passive networks which usually require separate networks for amplitude and delay distortion correction since each alteration of the amplitude characteristic of a purely amplitude corrective network introduces some delay distortion which in turn must be offset in the delay corrective network. For this reason, amplitude distortion correction is usually made first. With the $K=3$ active network, this process is inherently accomplished.

Application of Corrective Networks

A great variety of delay curve shapes may be encountered among the transmission circuits to be equalized with corrective networks. Not only are there large variations among the different types of circuits, but even the same type requires different amounts of correction throughout the essential frequency range. For any circuit to be corrected, the desired result to be achieved is a uniform amplitude and delay response flat within

prescribed limits over the essential band width. Since delay cannot be subtracted from the circuit, the problem resolves itself into one of raising the delay of all points to the vicinity of the highest delay value on the characteristic within the essential band width.

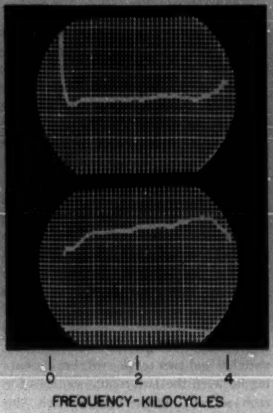

Fig. 12. Delay and amplitude characteristics of a 44-millihenry-per-mile loaded cable—corrected

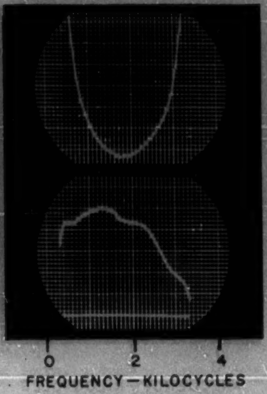

Fig. 14. Delay and amplitude characteristics of a type-K carrier circuit—uncorrected

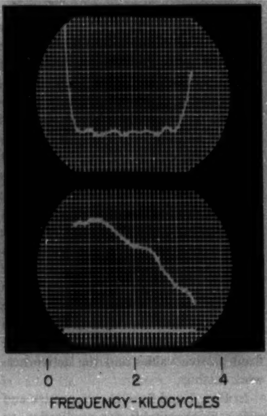

Fig. 15. Delay and amplitude characteristics of a type-K carrier circuit—delay corrected, amplitude uncorrected

The application of both passive and active networks is particularly advantageous in conjunction with the delay measuring instrument by which the delay characteristic is continuously displayed. The passive sections possessing relatively large lumped delay values, preferably are first inserted for a rough correction. After this has been done, the remaining correction may be accomplished with active network sections, and those areas filled in where delay deficiencies exist. The ability to vary the delay of each individual section allows much finer adjustments to be made than is practical with passive sections. If, after obtaining a refined delay correction, amplitude distortion exists as a result of insufficient amplitude correction, or amplitude distortion inserted by the passive sections, the amplitude characteristic may be corrected with some limitations by offsetting the adjustable resistors of the active network sections as described in the foregoing.

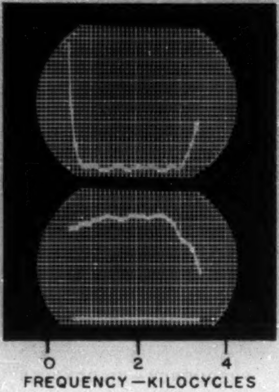

Fig. 16. Delay and amplitude characteristics of a type-K carrier circuit—corrected

In some applications such as in military circuits, it might be desirable to provide packaged units containing a number of passive sections and other units containing a number of active sections. In this case the units would be left in circuit as adjusted and would be available for making a quick change in case the circuit makeup is altered. In other cases this procedure would not be economical. The preferred method then would be to insert other passive and active sections in the circuit corresponding to the sections in use in the packaged units, or specially select or design passive sections which simulate the combined delay of the passive and active sections. The design parameters can be obtained from the fixed passive values and the active network settings.

In Figs. 7 and 8 are shown passive and active units suitable for application to facsimile circuits as discussed in the foregoing. The passive unit consists of 25 bridged-T sections and an input and output transformer. Each section has a fixed delay distribution and an attenuation at the frequency of peak delay ranging from about 0.8 decibel in the low-frequency sections to about 1 decibel in the upper frequency sections. The peak delay occurs at selected frequencies ranging from 600 cycles for section 1 to 3,000 cycles for section 25. A representative curve of the delay distribution of one section is shown in Fig. 9. The sections are arranged in four groups to simulate assigned delay distributions. Switches are provided to permit any group or any combination of sections to be inserted.

The active network unit consists of eight type $K=3$ sections as shown in Fig. 8 with electron tube coupling between sections, an input gain control, and a twin-triode output amplifier stage. The peak delay values of the sections occur at approximately 375 cycles per second intervals from approximately 600 cycles to 3,200 cycles, with slightly closer spacing around the center of the band. As with the passive network, each section may be individually inserted or omitted for any circuit correction. Toggle switches are provided on the panel of the unit for this purpose. In addition to providing individual section selection, this unit has the additional advantage of individually variable delay for each section. The delay is varied with two rotary switches and two toggle switches appearing between the two rotary switches for each section. With these controls the peak delay of any section may be varied in 22 steps from a minimum of about 100 microseconds to maximum of about 1,500 microseconds. When the sections are inserted in tandem, the delay at any frequency will be the sum of the individual section delays at that frequency. The amount of correction inserted may range from about 100 microseconds when only a few sections are in circuit to approximately 3,000 microseconds when all sections are included and set at their maximum peak delay values. When it is desirable to change only the delay distribution, the switches are set in pairs with the switches of each section at the same switch position. If in addition it is desirable to make an amplitude correction in the vicinity of the section peak delay frequency, the lower rotary switch of a pair is set forward for an increase in amplitude and backward for a decrease in amplitude. Representative curves of the delay and amplitude distributions of one section are shown in Fig. 10. Here the delay curves are displaced vertically with respect to each other to show their distribution clearly. The three delay curves depict settings as provided in the active unit near the minimum, intermediate, and maximum peak delay values. The amplitude curves correspond to the intermediate delay distribution for a flat amplitude characteristic, and for intermediate amplitudes peaked upward and downward.

In addition to their use in effecting a particular delay distribution at constant amplitude, these units also have the property that various amplitude distributions can be simulated at an essentially constant delay. For example, by proper switch settings a vestigial filter amplitude characteristic can be simulated at constant delay throughout the effective band width.

Results of Distortion Correction

Facsimile and data processing equipment are required to operate satisfactorily over various types of commercial and military circuits. and various combinations of these circuits. These transmission facilities consist of various physical, carrier, and radio circuits having a wide range of envelope delay distortion and often an appreciable amount of amplitude distortion. The over-all frequency range necessary to provide satisfactory operation depends upon the type of equipment employed, and such factors as double or vestigial side-band operation, etc. In general the transmission band most frequently employed extends from about 600 or 800 cycles to about 3,000 cycles for the most important frequencies contained in the signals. Frequencies involved in transmission near the carrier frequency are usually of greater importance than frequencies remote from the carrier frequency.

For application to facsimile circuits, a number of corrective sections are connected in tandem, usually at the receiving end of the circuit; the number depends upon the type of delay characteristic to be corrected. These sections are spaced at frequency intervals throughout the band as required to fill in a delay deficiency, and each active section is adjusted so that the combined delay of all sections is the desired delay compensating characteristic. In general, relatively broad individual curves spaced far apart are required when the delay to be corrected is small in value. Where a large value of delay needs to be corrected, relatively steep delay curves can be used with the sections spaced at small requency intervals

In Fig. 11 are shown the delay and amplitude characteristics of a 44-millihenry-per-mile loaded cable circuit approximately 125 miles in length. This circuit was corrected by use of the active network alone with the result as shown in Fig. 12 in which delay characteristics is flat within the usual allowable tolerance of ±250 microseconds from approximately 500 to 4,000 cycles. A rough amplitude correction was obtained by use of the active network as shown by the lower traces of these oscillograms. It should be noticed that since amplitude can be either added or subtracted, in the corrective process the amplitude was decreased for the lower frequencies and increased for the upper frequencies by the active networks. Likewise, in Fig. 13 are shown results as obtained on a radio beam circuit approximately 200 miles in length. The upper curve of this oscillogram is the delay characteristic without correction and the lower curve is the delay characteristic after correction has been applied. The corrective process is well illustrated by the oscillograms of Figs. 14–16, which utilize a long type-K carrier circuit. Fig. 14 shows the uncorrected delay and amplitude characteristics; in Fig. 15, the delay characteristic has been corrected; and Fig. 16, a partial amplitude correction has been obtained. It should be pointed out that in making the amplitude correction, the delay characteristic was unaffected and, for all practical purposes, the delay and amplitude corrections can be made independently of each other.

These networks provide a readily adjustable means for obtaining various delay characteristic shapes in addition to those normally present in facsimile circuits for the appraisal of facsimile recorded copy with respect to delay distortion. A large number of such test conditions have been investigated which comprise various tolerances from a mean value. For the loaded physical circuit, Figs. 11 and 12, facsimile operation is considerably improved by distortion correction. For type-K circuits distortion correction may give sufficient improvement to permit operation at double speed with vestigial operation as compared to double side-band operation with the carrier near a point of even symmetry on the delay characteristic. Also, delay distortion correction may permit splitting the normal voice band circuit into two subbands so that normal operating speed can be obtained in each of these bands by use of vestigial operation. In general, the appraisal of the various factors involved indicate that the tolerance limit for satisfactory facsimile operation is of the order of ±400 microseconds from the mean value per 1,000 cycles of modulation (inverse relationship), whereas the usual quoted value is generally ±250 microseconds.

Electrical Formulas in Inch Units of Length

J. W. WILLIAMSON
MEMBER AIEE

ELECTRICAL formulas in textbooks and periodicals are usually expressed in metric units of length (centimeters or meters). In many countries, including the United States, dimensions on shop drawings must be reduced to inches. In the past, the inconvenience and possibility of error in converting from metric to inch units have created at least a minor barrier between electrical theory and practical application. In addition, it has appeared that an engineer starting in industry must familiarize himself with a group of electrical equations which, usually being expressed in inch units of length, differed slightly from those learned in college.

Prior to the advent of the rationalized meter-kilogram-second (mks) system (properly referred to as the Giorgi system), it was indeed necessary to insert factors such as 2.54 and 10^{-8} into equations in which distances were in inches and electrical quantities in practical units. When such factors are combined with other factors, such as 2π and $\pi/4$, the resulting proportionality constants may be numerical expressions which have little meaning to the engineers who use them, with the result that these engineers may regard their work as a "crank-turning" process rather than the application of professional knowledge.

The break or divsion between industrial practice and educational training may be minimized if equations derived in metric units can be utilized without change when distances are in inches. It is shown that equations derived in the rationalized form (recommended by the International Electrotechnical Commission) of the mks system apply with distances in inches if appropriate values are used for the permeability μ_v and permittivity ϵ_v of vacuum.[1] New units are required only for mechanical force (the joule per inch, or "jupi") and mass (the "jupima").

The IJS Electrical Unit System

Being based on the inch as a unit of distance, the jupima as a unit of mass, and the second as a unit of time, the system of electrical units introduced in this paper is called the "ijs" system. It might also be called the "ijsa" system since currents are expressed in amperes and other electrical quantities in corresponding practical units.

The ijs system is merely a variation of the rationalized mks system in which distances are expressed in inches rather than meters. Table I gives a comparison between the two systems and also a comparison with a third rationalized unit system in which distances are expressed centimeters.

The Rationalized MKS and IJS Electrical Unit Systems

Such confusion exists about electrical units that a brief discussion or rationalized unit systems and how electrical formulas can be converted from the older unit

systems (which required that distances be expressed in centimeters) to the rationalized mks system or ijs system seems necessary. Consider the following equations

$$B=\mu_v H \text{ (in vacuum)} \tag{1}$$

$$D=\epsilon_v E \text{ (in vacuum)} \tag{2}$$

If corresponding definitions are adopted for B, H, D, and E, the equations 1 and 2 and all equations derived therefrom, apply in any consistant system of units.

Define a rationalized unit systems as one in which:

1. B is expressed in magnetic flux lines per unit area such that a rate of change of one magnetic flux line per unit time results in one unit of potential difference per turn.
2. H is expressed directly in current turns per unit length.
3. D is expressed in electrostatic flux lines per unit area such that one electrostatic flux line emerges from each unit of positive charge.
4. E is expressed in potential drop per unit length.
5. The unit of energy is equal to the unit of charge multiplied by the unit of potential difference.
6. The unit of mechanical force is equal to the unit of energy divided by the unit of distance.
7. The unit of mass is such that the unit of force, acting on the unit of mass, produces a unit acceleration.

These statements, together with selection of any four basic units (such as units of distance, mass, time, and current), are found completely to define an electrical unit system. All equations in any rationalized electrical unit system (as defined in the foregoing) are identical. Therefore, an equation derived in any rationalized unit system applies in any other rationalized unit system.

According to the definitions of a rationalized system, if potential differences are in volts, magnetic flux lines must be in webers (1 weber $=10^8$ ordinary magnetic flux lines or maxwells), so that a rate of change of one magnetic flux line per second will produce one volt per turn. Therefore, in rationalized mks units, the magnetic flux density B is in webers per square meter. The magnetic field strength H is in ampere-turns per meter; the electric displacement D in electrostatic flux lines per square meter each electrostatic flux line emerging from a positive charge of 1 coulomb; the electric field strength E is in volts per meter; the unit of energy in 1 coulomb × 1 volt = 1 joule; the unit of force is a joule per meter, which is also called a newton; and the unit of mass is such as to require a force of one newton to produce an acceleration of 1 meter per second squared (m/sec²). This unit of mass turns out to be a kilogram.

In the ijs system, potential differences are again in volts, and time is again in seconds. Therefore, magnetic flux lines are in webers. The magnetic flux density B is in webers per square inch. The magnetic field strength H is in ampere-turns per inch; the electric displacement D in electrostatic flux lines per square inch, each electrostatic flux line emerging from a positive charge of one coulomb; the electric field strength E is in volts per inch; the unit of energy is again 1 coulomb × 1 volt = 1 joule; the unit of force is a joule per inch, which is called a "jupi"; and the unit of mass (called a "jupima") is such as to require a force of 1 jupi to produce an acceleration of 1 inch per second squared (in./sec²).

Permeability and Permittivity of Vacuum

The permeability of vacuum is defined as the permeance of a magnetic flux path 1 unit of length × 1 unit of length in cross-sectional area and 1 unit of length long. There is very nearly 0.0254 meter in an inch. It follows that the permeability of vacuum expressed in inch units of length is very closely $0.0254^2\times(1/0.0254)=0.0254$ times as great numerically as the permeability of vacuum expressed in meter units of length. Similarly, the permittivity of vacuum in inch units of length is approximately 0.0254 times as great numercially as the permittivity of vacuum in meter units of length. Hence, starting with values of permeability and permittivity in metric units,

$$\mu_v=4\pi\times10^{-7}\,\frac{\text{webers/meter}^2}{\text{amp (turn)/meter}} \text{ or}$$

$$4\pi\times10^{-7}\,\frac{\text{henries}}{\text{m}} \text{ (with distances in meters)}$$

or

$$\mu_v=3.1919\times10^{-8}\,\frac{\text{webers/inch}^2}{\text{amp (turn)/in.}} \text{ or}$$

$$3.1919\times10^{-8}\,\frac{\text{webers}}{\text{in.}} \text{ (with distances in inches)}$$

and

$$\epsilon_v=8.8549\times10^{-12}\,\frac{\text{coulombs/m}^2}{\text{volt/m}} \text{ or}$$

$$8.8549\times10^{-12}\,\frac{\text{farads}}{\text{m}}$$

(with distances in meters)

or

$$\epsilon_v=2.2491\times10^{-13}\,\frac{\text{coulombs/in.}^2}{\text{volt/in.}} \text{ or}$$

$$2.2491\times10^{-13}\,\frac{\text{farads}}{\text{in.}}$$

(with distances in inches)

Conversion of Electrical Equations from Other Unit Systems

Frequently it may be desired to convert an equation derived in one of the older unit systems to make it apply in rationalized mks or ijs units. Since these older systems were designed to make B numerically equal to H in vacuum (the centimeter-gram-second (cgs) electromagnetic and practical systems), D numerically equal to E in vacuum (the cgs electrostatic system); or both $B=H$ and $D=E$ in vacuum (the Gaussian and Heaviside-Lorentz systems), equations derived therein may be suspected of containing what might be called a "suppressed" μ_v or ϵ_v. Referring back to equations 1 and 2, it should be apparent that the numerical values of μ_v and ϵ_v must change if, for example, the unit of distance is changed. Therefore, μ_v and ϵ_v must be included in equations 1 and 2, and in all equations derived therefrom, for a system of electrical units applicable in any consistent units. The test of whether or not an electrical equation is applicable in any consistent units is to determine whether the dimensions of the left side are the same as those of the right side without assuming either inductance or capacitance to be expressible in centimeters. If the dimensions of the left side differ from those of the right side, it may be assumed that either μ_v or ϵ_v must be added in such a way as to make the equation dimensionally correct in a rationalized sense, in this process of course not changing the numerical value of the right side of the equation in the original system of units. As a simple example, the inductance (henries) of an N-turn coil of length l centimeter (cm) wound about a core of cross-sectional area A centimeter squared (cm²), the length l being much greater than the dimensions of the cross section, is sometimes expressed:

$$L=4\pi\times10^{-9}\,\frac{N^2A}{l}$$

The dimensions of the left side are henries, while the dimensions of the right side are centimeters. However, in reference to Table I, the permeability of vacuum in the practical electrical unit system based on the centimeter as a unit of length is

$$\mu_v=4\pi\times10^{-9}\,\frac{\text{webers/cm}^2}{\text{amp (turn)/cm}}=4\pi\times10^{-9}\,\frac{\text{henries}}{\text{cm}}$$

Hence

$$L=\mu_v\,\frac{N^2A}{l}$$

is correct both numerically and dimensionally and applicable in any rationalized unit system.

As a more complicated example, the "equivalent depth of current penetration" of induction heating is frequently written:

$$d=(1/2\pi)\sqrt{\rho\times10^9/f}$$

d being the depth of current penetration in centimeters, ρ the resistivity of the material in ohm-centimeters, and f the frequency in cycles per second. This equation also is not dimensionally correct in a rationalized sense, but may be replaced by

$$d=\sqrt{\rho/(\pi f\mu_v)}$$

which is dimensionally correct and applicable in any rationalized unit system.

The mks system is not always used in its rationalized form. For example, some well-known books by the staff of the Massachusetts Institute of Technology express the magnetic field strength H in units (praoersteds) such that H is equal to the ampere-turns per meter multiplied by 4π, and the electric displacement D in an electrostatic flux lines per unit area, each of which emerges from a positive charge of $(1/4\pi)$ coulombs. The definitions of magnetic flux density B, electric field strength E, and all other quantities are identical with those in the rationalized mks system. Letting μ_0 stand for B/H and ϵ_0 stand for D/E in unrationalized mks units (all in vacuum); and μ_v and ϵ_v stand for the same ratios in rationalized mks units,

$$\mu_0=(1/4\pi)\mu_v \tag{3}$$

$$\epsilon_0=4\pi\epsilon_v \tag{4}$$

Equations derived in unrationalized mks units apply in rationalized mks or ijs units unless they contain any of the four quantities H, D, μ_0, ϵ_0. In this case the differences in definition and numerical value must be kept in mind in rationalizing.

Units of Force and Mass

In referrence to the characteristics of a rationalized electrical unit system (some of which apply to unrationalized systems also), the unit of force is equal to the unit of energy divided by the unit of distance. Hence, forces come out in joules per inch or newtons in the mks system, or joules per inch or "jupis" in the ijs system.

$$1\text{ jupi}=\frac{1\text{ joule}}{1\text{ in.}}=\frac{10^7\text{ dyne cm}}{2.54\text{ cm}}=(1/2.54)\times10^7\text{ dynes}=8.851\text{ pounds}$$

The unit of mass such as to require a jupi for an acceleration of 1 in./sec² is

$$1\text{ jupima}=\frac{1\text{ jupi}}{1\text{ in./sec}^2}=\frac{(1/2.54)\times10^7\text{ dynes}}{2.54\text{ cm/sec}^2}=(1/2.54)^2\times10^7\text{ grams}=1.5500\times10^6\text{ grams}$$

The approximate mass of an electron is 9.10×10^{-28} grams $=5.87\times10^{-34}$ jupimas.

Conclusions

The system of electrical units proposed (the ijs system) is not intended to replace the rationalized mks system, but to form an auxiliary system in which all equations are identical with those of the rationalized mks system. This permits utilization without change of equations derived in metric units, with distances in inches. The joule per inch or "jupi" as a unit of force and the "jupima" the corresponding unit of mass, may be used by electrical engineers in practical design calculations in much the same way that mechanical engineers express mass in "geepounds" or "slugs." The result in both cases is that equations derived in metric units in theoretical texts apply also in units convenient for every day use.

Some of the units in the ijs system appear inconveniently large. The magnetic flux density B comes out in webers per square inch. The milliweber per square inch would be a convenient unit for industrial design data, since the saturation flux density of iron at room temperature is approximately 1.4 milliwebers per square inch; it is worth remembering that the corresponding rms flux density is approximately 1 milliweber per square inch. The unit of electrostatic flux density D is also very large, but this appears to introduce no problems. In making a magnetic or electrostatic flux plot, one line or tube of force would stand for only a small fraction of a line of B or D as defined in this paper. While the "jupima" = 1,550 kilograms might be considered an inconveniently large unit of mass for a particle as small as an electron, actually it makes little difference whether the mass of the electron be expressed in milligrams or tons, since multiplication by 10 raised to an exponent is required for convenience in either case.

An equation derived in one of the older unit systems may be rewritten in rationalized form. When the equation is rewritten, care should be taken that all quantities involved are defined according to the rules stated in the foregoing for a rationalized system of electrical units. The equation should be checked to determine whether the dimensions of the left side reduce to those of the right side without assuming inductance or capacitance to be expressible in units of length, such as centimeters. If the dimensions of the left and right side do not agree, the permeability μ_v or permittivity ϵ_v of vacuum must be inserted in such a way as to make the dimensions of the left side the same as those of the right side. The manner in which μ_v or ϵ_v is inserted must, of course, be such as not to change the numerical value of the right side of the equation in the original system of units.

While the permeability and permittivity of vacuum may be converted from metric to inch units by following familiar rules, such as would be used for the conversion of electrical resistivity, the approximate numerical values should be memorized. These are

$$\mu_v = 3.19\times10^{-8}\,\frac{\text{webers/in.}^2}{\text{amp (turn)/in.}}$$

$$= 3.19\times10^{-8}\,\frac{\text{henries}}{\text{in.}}$$

$$\epsilon_v = 2.25\times10^{-13}\,\frac{\text{coulombs/in.}^2}{\text{volt/in.}}$$

$$= 2.25\times10^{-13}\,\frac{\text{farads}}{\text{in.}}$$

A New Technique for the Measurement of Corona Field Strength and Current Density in Electrical Precipitation

P. COOPERMAN
NONMEMBER AIEE

IN THE course of studies of the electrical precipitation of gas-borne dust, it became necessary to determine the electric-field strength in the negative space-charge region of a corona discharge in room air. However, no satisfactory technique for making such measurements was known to the writer or to the persons whom he consulted, nor did a brief survey of the literature offer anything of use. A number of attempts were made to use static probes of types encountered in electrostatics, but these were uniformly unsuccessful. Hence, it became necessary to develop an instrument based on a new principle. This principle makes use of the laws governing the charge picked up by a particle in a unipolar space-charge field as a function of field strength, current density, and time. Essentially, the quantities measured are the particle charge and the time spent by a particle in the field. By the use of the particle-charging laws, the values of the field strength E and of the current density i may be deduced.

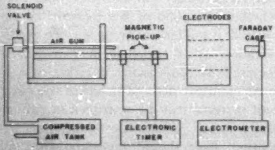

Fig. 1. Schematic diagram of the apparatus

The technique was not pushed to a high level of accuracy because this was not necessary to the use for which it was intended. Nevertheless, it is felt that, in spite of this defect, the possibilities of this method make publication desirable.

Theory

The probe operates by firing precision steel ball-bearings of 3/16-inch diameter from an air-gun, through the discharge under investigation, and into a Faraday cage where the charge picked up is measured by an electrometer. A schematic drawing of this arrangement is shown in Fig. 1. The charge picked up by a steel ball is subject to the laws of particle-charging in unipolar fields[1] which for present purposes may be written, in electrostatic units (esu)

$$V^{-1} = V_s^{-1}(1+v/v_0) \tag{1}$$

$$V_s = 3a^2E/C \tag{2}$$

$$v_0 = \pi Lj/E \tag{3}$$

where

V = voltage in Faraday cage
v = velocity of ball
C = capacitance of Faraday cage + electrometer + cables
L = length of trajectory within discharge
a = radius of ball

Equation 1 indicates that a plot of V^{-1} against v for spheres projected along a given trajectory should be a straight line with intercepts V_s^{-1} and $-v_0$. These quantities determine E and i through equations 2 and 3. A sample plot is shown in Fig. 2.

The foregoing shows that where more than two velocities are used for a given trajectory, deviation of the plotted points from a straight line is an indication of experimental error, or of an incompatibility of the experimental conditions with the hypotheses of particle-charging theory. Thus the new measurement technique to a certain extent has proved self-checking.

Apparatus

The air-gun consists of a barrel 2 feet in length, with an inside diameter of 3/16 inch (+0.001, −0.000 inch), a pressure tank storing air in the range of 0–125 pounds-per-square-inch gauge, and a solenoid control valve. The barrel is

mounted on a long bar which also contains two magnetic pickups feeding into an electronic timer. The bar, in turn, is mounted in a framework which permits horizontal and vertical adjustments in steps of 1/2 inch. After traversing the discharge, the shots are caught in a Faraday cage. The inner cylinder is of 1-inch diameter and 2-inch length, and is shielded by an outer cylinder of 2-inch diameter and 12-inch length. The back end of the cage is fitted with a coaxial connector from which a cable runs to a Cenco-Dershem electrometer.

It has been found that the usual braided shielding of coaxial cable is not sufficient to prevent pickup of stray ions from the discharge. This is easily overcome by wrapping the cable with aluminum foil. With this precaution, the electrometer holds steady at its zero reading until a shot is fired. After the firing of the shot the electrometer holds the new reading indefinitely.

Experimental Results

The first series of experiments was conducted on a set of coaxial cylinder electrodes consisting of an 8-inch tube and a steel wire of 0.109 inch in diameter. Since the electric field for this geometry has already been investigated both theoretically[1,2] and experimentally,[1] the object of these tests was to compare the measured values of E with those calculated from the equation, in esu

$$E^2=(r_0E_0/r)^2+2i/k \tag{4}$$

where

E_0 = "critical" field strength for starting corona
r = radial distance from center of wire
r_0 = wire radius
i = current per centimeter (cm) length of electrode
k = ion mobility

E_0 was calculated from the semiempirical equation given by Peek.[3] The mobility k was taken to be 660 cm² per statvolt seconds, in accordance with data given by Loeb.[4] Comparison of measured and calculated values of E was the only quantitative check on the results obtained by this probe, since attempts to measure E by other methods were not successful.

Table I. Comparison of Calculated and Measured Values of E and j at Various Voltages for r=9.2 Cm

Corona Voltage, Kv	E Measured	E Calculated	j Measured	j Calculated
40	5.9	5.4	360	250
50	11.1	10.4	750	590
60	14.0	15.1	1,270	1,250

All values are in esu except for the voltage.

Fig. 3 is a graph of E versus r for an applied voltage of 50 kv. The curve represents the values computed from equation 4, while the experimental re-

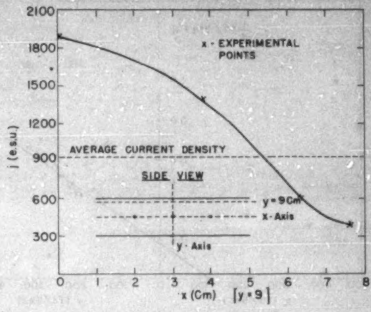
Fig. 7 (right). Current-density versus distance along line y=9 cm in duct geometry



sults are indicated by crosses. It can be seen that the maximum deviation of the experimental from the theoretical values is about 10 per cent (%). Fig. 4 is a similar plot of j versus r and the corresponding maximum deviation is about 30%. As an additional check, data were taken on a line for which r was 9.2 9.2 cm. at applied voltages of 40, 50, and 60 kv; the results are given in Table I. Here again the deviation of the measured from the theoretical values of E and j are of the order of 10% and 30% respectively. Notice also that the measured values of E and j at 50 kv are in fair agreement with the previously measured values of 10.0 and 720 esu respectively.

The next series of measurements was conducted on corona discharge in duct geometry. The geometry produces low current densities as compared to the coaxial cylinders, which in turn results in greater scatter in the data. To improve this condition without redesigning the equipment, 0.020-inch wire was substituted for that of 0.109 inch previously used. In addition, the reliability of the results was increased by taking 20 to 30 shots and determining the values of E and j by least-square calculations. With these precautions, the reproducibility of the results was of the order of 5% in field strength and 10% in current density, at points where the current density was greater than about 1,000 esu.

To illustrate the results obtained, some of the more important features will be described of the field configuration for electrodes consisting of three 0.020-inch wires spaced 6 inches apart in a plane parallel to, and midway between, a pair of plates spaced 8 inches apart. Each plate was made up of a 2- by 1-foot strip surrounded by a guard plate of 29 by 32 inches. At 50-kv applied voltage, the average current density was 930 esu. Fig. 5 is a plot of field strength versus distance from the plane of the wires along the line of force running from the center wire to a plate. Note that the field strength is about 10% above average at the surface of the plate, and that it dips to about 36% below average at 2.2 cm from the wire, and then starts rising again.

A strong argument can be given to support these observations. In the immediate vicinity of a flat plate, the lines of force must very closely approximate straight lines perpendicular to the plate. Consider a small rectangle contained between two lines of force, and two equipotential lines consisting of a small portion of the plate itself and another equipotential. For a negative space charge,

$$E_P - E_Q < 0 \qquad (5)$$

where

E_P = field-strength at the plate
E_Q = field-strength at the opposite side of the rectangle

Hence E_P is greater in absolute magnitude than E_Q. This leads to the statement that the field strength, at a point on the surface of a flat plate, is greater in magnitude than at any other point which is within a certain distance from it and located on the same line of force. Obviously, this argument does not apply when the electrodes are curved.

A second supporting point arises from the fact that the data were taken along a line of force. Hence, numerical integration of the field strength along this line will give the potential, which in this case turns out to be 36.7 kv at $y = 1.6$ cm. This is about 10 kv higher than the calculated, purely electrostatic potential at that point. Since space charge acts to reduce the field which produces it, i.e., the field in the neighborhood of the wire, this potential differs from the electrostatic potential in the right direction. This gives at least qualitative support to the results shown in Fig. 5.

Field strength and current distribution along a line parallel to the plane of the wires but perpendicular to the wires themselves, and at a distance of 9 cm, is shown in Figs. 6 and 7. The field strength, starting from a value of about 18 esu opposite the center wires, declines gradually to 16, and then rises suddenly to about 27 esu at a point midway between two wires. This sudden rise has not yet been explained on a theoretical basis. However, other workers in this laboratory, using an electrical precipitator of similar geometry to collect oil-mist droplets, have noticed heavy sootlike deposits on the plates along lines parallel to and midway between corona wires. A plausible explanation of this phenomenon is that the deposits are due to particles of varnish formed from the oil and collected at these points by an exceptionally high field. This view offers partial confirmation for the measured values of field strength. In contrast to this unusual behavior, the current-density curve follows the expected pattern of being maximum at a point opposite a wire and declining monotonically to a minimum value at a point midway between the wires. Although the line $y = 9$ cm is not an equipotential, its proximity to a plate implies that it does not differ very much from an equipotential. Hence, numerical integration of the current density should given an approximate value for the total current. The value so obtained turns out to be about 30% higher than the current read by a milliammeter.

Errors

The major part of the error in these results is due to the generation of spurious charges in the Faraday cage under impact of the shots. This was shown to occur by firing shots through a sheet of aluminum foil covering the mouth of the cage with the discharge turned off. Under these conditions, electrometer readings in the range of 0–0.25 volt were obtained, with an average of about 0.1 volt. All readings were of the same sign. Since in normal operation, readings of 1 to 4 volts are obtained, one sees that the percentage error due to spurious charges will vary with the charge picked up by the shots. In general, the percentage error will be high for low current densities and low for high current densities. For those of over about 1,000 esu, ~0.3 milliamperes per foot,[2] the values of E and i were reproducible to within ±5% and ±10 % respectively.

Conclusions

The probe method discussed here has been used to measure field strength and current density in electrical precipitators. For cylindrical geometry, the measurements were in fair agreement with theory and with previous measurements. In duct geometry, the results indicate that the field strength reaches a minimum in the space between the discharge and passive electrodes. The current density along the plate goes from a maximum value opposite a discharge wire to a minimum at a point midway between wires. There are indications that the field strength at the plate surface is maximum between the wires; however, this result is uncertain because of the error associated with the low current density at these points.

These results indicate the following with regard to duct precipitators:

1. The charge on collected particles may be higher than would be expected, since these particles must get into the high-field region near the plates.
2. For the same reason, the drift velocity of particles, due to the electrical field, may be higher near the plates than would be estimated from the average field strength.
3. For high current-density types of precipitators, i.e., $j > 0.1$ milliamperes per foot[2], efficiency may be a function of current, rather than of voltage.

A New Five-Digit Plugboard System for Card-Programmed Calculator

S. B. WILLIAMS
ASSOCIATE MEMBER AIEE

MISS N. M. NOONAN
NONMEMBER AIEE

THE International Business Machines Corporation's card-programmed calculator (CPC) is one of the most extensively used automatic digital computers in the world today and has been discussed in several technical articles.[1-4] Scientific calculations, engineering problems, and accounting procedures have all been applied to the CPC with success. This flexibility may be attributed to the fact that all of the computer elements of the CPC are wired to plugable terminals on removable plugboards as shown in Fig. 1. Thus, by changing wires on the plugboard, the internal design of the CPC may be altered and optimized for a particular application. The purpose of this paper is to present the features of a new CPC plugboard system developed by the Power Transformer Engineering Section of the General Electric Company primarily for engineering design calculations. This system may be used for any calculations where slide-rule accuracy is adequate.

History and Scope

In late 1953, when the application of a a digital computer to the transformer design problem was being studied,[5] it became apparent that although simple, 2-winding transformers could be handled adequately by existing CPC plugboard systems, the extension into 3-winding transformers and autotransformers would require more memory capacity. Several CPC users have increased memory capacity by adding more units. This prospect did not appear attractive either from the standpoint of fitting these devices into the basic machine design or from the standpoint of extra rental fees. For these reasons it was decided to explore the possibilities of a new plugboard system. Since slide-rule accuracy is usually adequate for design calculations, and the location of decimal points is more easily predictable for design calculations than for more abstract mathematical calculations, a 5-digit floating-decimal general-purpose CPC plugboard system was studied and developed. The primary difficulties encountered in this project stemmed from the fact that the CPC is basically a 10-digit machine and many of the machine elements are so designed. This has resulted in some minor inconveniences for the machine programmer but they are far outweighed by the advantages.

Since the 5-digit system has been in use for over 1 year and several 10-digit programs have been directly converted to it, an evaluation of its effectiveness for engineering design applications has been made. The following advantages have resulted:

1. The memory capacity of the CPC is effectively doubled, enabling more difficult and involved problems to be processed on it.
2. The calculating speed of the CPC has been increased about 60 per cent with corresponding time savings.
3. The ability of the CPC to perform logical decisions and determine alternate courses of action has been increased substantially; consequently more decision-type calculations can be performed at a higher speed.

All of these advantages have been secured with no increase in rental fees and with more than adequate accuracy of results.

The discussion of any computer system entails a description of the various computer elements and the ways in which these elements work together to accomplish the desired results. Some of the features which are described in this paper

Paper 56-143, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 24, 1955; made available for printing November 23, 1955.

S. B. WILLIAMS and MISS N. M. NOONAN are with the General Electric Company, Pittsfield, Mass.

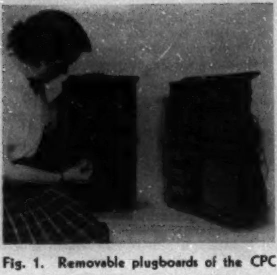

Fig. 1. Removable plugboards of the CPC

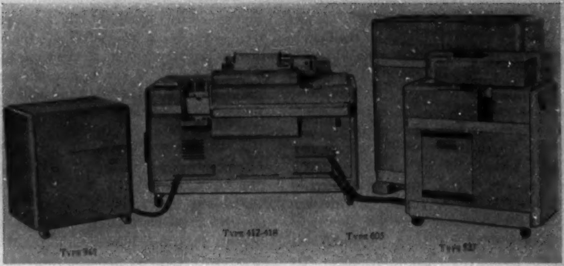

Fig. 3 (above). Machine components of the CPC

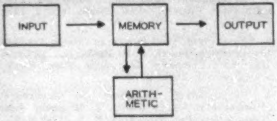

Fig. 2. Basic organization of functions, digital computer

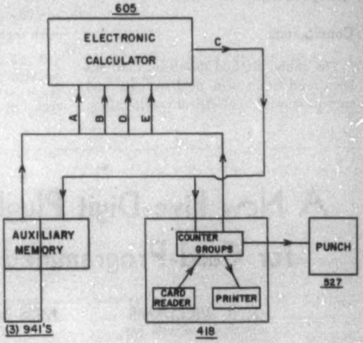

Fig. 4 (right). Schematic organization of the CPC

are common to most CPC plugboard systems and some are peculiar to the 5-digit system under discussion. A knowledge of all of these is necessary, however, for a full understanding of how the 5-digit system operates to perform useful calculations.

Organization

All digital computers from the smallest to the largest so-called giant brains have five main functions: input, memory, arithmetic, output, and control. The first four of these functions are shown schematically in Fig. 2. Control, or the diversion of information from function to function, is implied throughout the entire system. The differences among the various computers available today are in the physical forms that these functions may take, in the capacities of the functions, and in the speed with which information or data can be moved from one to another.

The card-programmed calculator installed in the Power Transformer Engineering Section at Pittsfield, Mass., is shown in Fig. 3 and consists of a type-*418* accounting machine, three type-*941* memory units, a type-*605* electronic calculator and a type-*527* summary punch machine. These units are interconnected in accordance with the organization requirements of a digital computer by appropriate wires in a plugboard system. Fig. 4 shows these interconnections and the location of the functional components which will be described in detail.

INPUT

Input to the CPC is in the form of standard International Business Machine cards, each of which is punched according to a prearranged system. The cards are interpreted by a card reader on the type-*418* accounting machine at a rate of 150 per minute. The time required to read one card (0.4 second) is called a card cycle. There are three different types of cards required to make up a complete CPC program: the control card, the data card, and the instruction card.

The Control Card contains punches which direct or order several mechanical operations of the CPC. For example, such a card might tell the machine to prepare to receive data, print or punch out results, space the printed form, skip to the first line of the next page, etc. A typical control card is shown in Fig. 5.

After the CPC has been told by a control card to prepare to receive data, a data card follows, containing digit punches which tell the CPC what the values of the variables are for the particular calculation being performed. Each datum number which is processed in this system has five digits. The first four digits of each number are the significant digits of that number. The last digit locates the decimal point with the digit 4 selected as the zero base. Therefore, within the range of $(1.000) \times (10)^{-4}$ to $(9.999) \times (10)^{5}$, any number may be converted to an equivalent CPC datum number as follows: Normal number $(n.nnn) \times (10)^{p} = nnnn(p+4)$, the equivalent CPC datum number. This 5-digit number can then be punched onto a data card and readily interpreted by the machine. Negative numbers are indicated by an x double punched into the fifth column of the datum number. The following examples help to illustrate this feature:

Normal Number	Equivalent CPC Datum Number
1	10004
1000	10007
0.001	10001
45.73	45735
−1.23	$1230\overset{x}{4}$

As many as eight 5-digit numbers can be punched into one data card and all of these numbers are transferred to the memory of the machine at one time. A typical data card is shown in Fig. 6.

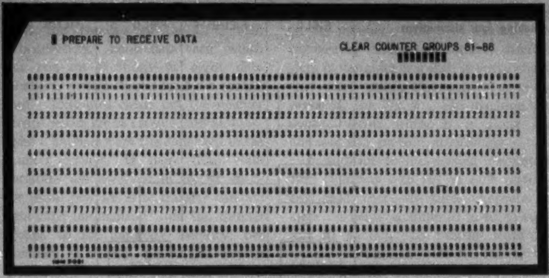

Fig. 5. Typical control card

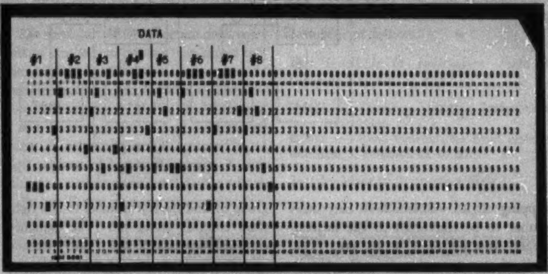

Fig. 6. Typical data card

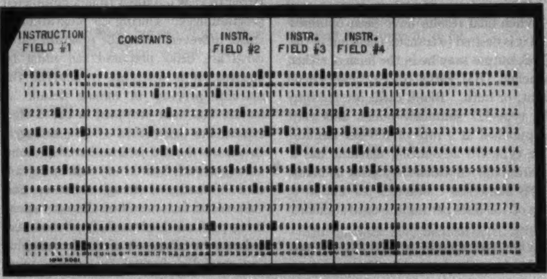

Fig. 7. Typical instruction card

Once the desired data have been transferred to the memory of the CPC, instruction cards follow which tell the machine what to do with the data. These cards contain punches which tell the machine where the data may be found in memory, what arithmetical operations to perform on the data, and where in memory to transfer the result of the operations. To take the machine through the desired calculation, one or several instruction cards would be required. Very difficult calculations sometimes require hundreds or even thousands of such cards. A typical instruction card is shown in Fig. 7.

MEMORY

There are two types of electromechanical memory in the CPC: counter group memory in the type-*418* accounting machine and auxiliary memory in the type-*941* units. The counter groups can store 12 5-digit numbers with their signs. In each *941* unit there is capacity for 16 10-digit numbers with their signs. In the 5-digit system, being described, the 10-digit registers have been apportioned into two 5-digit storage devices, but the two 5-digit numbers in one register must have the same sign. This has not been a serious limitation for the types of calculations performed with this system.

Each of the 5-digit memory positions has been assigned a location number or address. The counter groups are numbered 81–88 and 91–94. The auxiliary memory registers are numbered 11–18, 21–28, 31–38, 41–48, 51–58, 61–68. To differentiate between the left and right halves of the *941* registers, an x is double-punched over the low-order digit of the proper address to indicate the left five digits. In this way, address $2\overset{x}{4}$ refers to the left five digits in register 24 while 24 alone refers to the right five digits. Any of these addresses punched into the proper position on an instruction card will transfer the 5-digit datum number in the memory unit with that address to the electronic calculator. The total memory capacity of the CPC using this system is 108 5-digit numbers. Counters 81–88 have a special significance in the system being discussed. As each data card passes through the machine, direct channels have been provided from the *418* reader to these counters so that the datum number punched in columns 1 to 5 is transferred to counter 81, the datum number in columns 6 to 10 is transferred to counter 82, etc. In this way, eight data numbers may be read into the CPC at one time.

It is interesting to point out that transferring a number from a memory unit to the calculator or to some other location does not destroy that number in the memory unit. It remains there until a different number is directed into that memory unit.

ARITHMETIC

All arithmetical operations for the CPC are performed in the type-*605* electronic calculator. As each instruction card passes through the CPC, four data numbers may be sent into the *605* from either the counter groups or auxiliary memory over four electrical channels provided between these units. These data numbers or factors are called A, B, D, and E. The result of the operations on these factors is called C and it may be sent to the counter groups or auxiliary memory or used as any one of the four factors for the next instruction card. Mathematically, this relationship may be expressed as

$$[(A \text{ op } B)\text{op } D]\text{op } E = C$$

where op may be one of the basic arith-

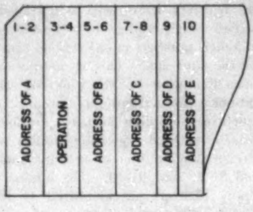

Fig. 8. Instruction field

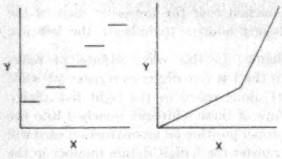

Fig. 9. Typical design functions

metical operations, +, −, ×, or ÷. The 5-digit system, being discussed, makes possible 60 different combinations of arithmetical operations on the four factors during each instruction card cycle.

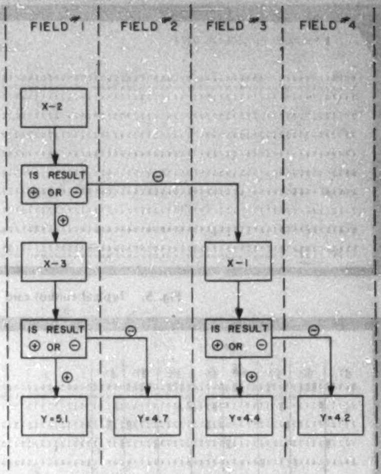
In addition to the arithmetical operations, one of several transcendental functions may be called for on an instruction card. These are:

$\sin A = C$
$\cos A = C$
$e^A = C$
$1 - e^A = C$
$\ln A = C$

Since the *605* calculates these functions by expanding the appropriate power series and many terms of these series are sometimes necessary to obtain the desired accuracy, calculation of transcendental functions requires more than one card cycle. When this is the case, the *418* card reader will stop feeding cards until the calculation is completed. A program deck containing many transcendental operations will run substantially slower than one containing only arithmetical operations.

Two other very useful operations which can be performed in the *605* are dropping digits and rounding. The machine can be instructed to drop all digits to the right of a certain decimal location. This is particularly useful in engineering design applications where many variables are discrete in size.[5] The dropping-digits operation allows any raw number to be converted to the next lower or higher integer, multiple of 2, 4, 10, etc. The machine can also be instructed to round or half adjust any number before dropping digits. This allows any raw number to be converted to the nearest integer, multiple of 2, 4, 10, etc. The result of any operation *C* in the *605* is always in floating decimal form.

Fig. 10. Form of program having four alternatives



Output

When final results have been obtained and it is desired to transfer them out of the CPC, output may be in the form of either punched IBM cards or a printed document, or both. Blank cards are fed into the type-*527* summary punch and may be punched at a rate of 100 per minute. The type-*418* accounting machine has a printing device which may print as many as 88 numerical characters per line at a rate of 150 lines per minute onto standard forms.

When the counter groups (81–88) are loaded from the data cards, the same data numbers are printed onto the output sheet. This gives the operator or interested engineering specialist an opportunity to check the accuracy of input data. It also provides a check between input data and output data for later reference.

Just as the eight counter groups may be loaded simultaneously from a data card, the same counter groups may be unloaded simultaneously to the *527* punches or to the *418* type-bars or to both. By appropriate punches on a control card, the desired information is made available to the CPC operator in punched or printed form in the same positions as the numbers on a data card, i.e., the first number to the left comes from counter group 81 and the last number to the right from counter group 88. The punched card will look exactly like a data card and may be used as such for future calculations if desired.

All of the output described has referred to that obtained from a completed program deck. During the programming stage, however, when the program cards cards are being prepared and must be checked, it is desirable to analyze the machine program in minute detail. A feature has been provided in the 5-digit system for doing this. When a toggle switch on the *418* is transferred, a complete printed listing of each program card is made, showing addresses and values of all factors and results, operations being performed, etc. This printed record may be taken away from the machine and carefully checked for programming errors.

Card Program Deck

The sequence of instructions to a digital computer directing it to perform a complete calculation is called a "program." With the CPC, this program consists of control, data, and instruction cards combined into a set of cards called a program deck.

The size of a program deck varies with the length and complexity of the calculation being performed; however, the form of each program deck is usually the same. Since no calculation can be performed until numbers are available on which to operate, the first part of a program deck loads the memory of the CPC with data numbers. Each data card, which can contain as many as eight data numbers, must be preceded by a control card. This card clears out the counter groups which are to receive data and provides a channel from the data card to the counter groups. If more than eight variables are involved in the problem, the usual practice is to transfer the first data-card information from the counter groups to the auxiliary memory, two numbers at a time, reload the counter groups with a second data card, transfer this information to auxiliary memory, etc., until values for all the variables are located in CPC memory.

The next part of the program deck consists of instruction cards which direct the machine through the calculations required. Each instruction card contains an instruction field as shown in Fig. 8. Columns 1 and 2 contain the 2-digit address of factor *A*, columns 5 and 6 contain the 2-digit address of factor *B*, column 9 contains the double-punched 2-digit address of factor *D* and column 10 contains the double-punched 2-digit address of factor *E*. Columns 3 and 4 contain the operation code which tells the machine what to do with the four factors. Columns 7 and 8 contain the 2-digit address of the result *C*. Up to three arithmetical operations may be performed on each instruction card as explained before. Two other features of the 5-digit system may be discussed here.

CONSTANTS

Columns 11 to 30 of each instruction card are reserved for constant values of the factors *A*, *B*, *D*, and *E*. A special address code tells the machine that the desired number is on the card rather than in memory. For example, if π is required as factor *A* on a particular instruction card, the number 31424 would be punched into columns 11 to 15; if 2 is required as factor *B* on an instruction card, the number 20004 would be punched into columns 16 to 20, etc. Thus, constants do not occupy valuable memory space.

ALTERNATE FIELDS

Columns 31 to 60 of each instruction card are reserved for alternate instruction fields. One of the most powerful features of the digital computer is its ability to recognize the magnitude of a number generated in a calculation and proceed on different courses of action depending on the number's size. For example, in engineering design calculations, discrete steps in variables or a shift in curve shape may occur within the range of a given problem; see Fig. 9. The machine can readily decide where it is along the abscissa and proceed accordingly.

In addition to the normal instruction field (columns 1 to 10) on each instruction card, there are three alternate instruction fields (columns 31 to 40, 41 to 50 and 51 to 60). To transfer from the normal instruction field to one of the alternate fields, an arithmetical operation is performed and the machine is instructed to sense the sign of the result. There are three different tests that may be made, as follows.

Test 1—Made in Instruction Field 1, Columns 1 to 10

Result +, Continue reading instructions from instruction field 1.
Result −, Read instructions from instruction field 3, columns 41 to 50.

Test 2—Made in Instruction Field 1

Result +, Continue reading instructions from instruction field 1.
Result −, Read instructions from instruction field 2, columns 31 to 40.

Tests 3—Made in Instruction Field 3

Result +, Continue reading instructions from instruction field 3.
Result −, Read instructions from instruction field 4, columns 51 to 60.

For example, if an operation of the following form must be programmed:

If $0\leq x<1$, then $y=4.2$
If $1\leq x<2$, then $y=4.4$
If $2\leq x<3$, then $y=4.7$
If $3\leq x$, then $y=5.1$

the CPC program would be of the form shown in Fig. 10; the machine interprets 0 as +.

The machine may be instructed at any time to return to instruction field 1 and continue the normal calculation.

With the use of all the features just described, the desired calculations may be performed. When results have been obtained and stored in memory, it is necessary to get them out of the machine so they may be read and interpreted by the machine operator or interested engineering specialist. The last part of the program deck consists of instruction cards which transfer the results to the counter groups 81 to 88, and a control card which directs the machine to print or print and punch these result numbers out as explained before. If more than eight results are desired, this procedure may be repeated until all results are out of the machine.

Once a program deck has been prepared and thoroughly checked, it is necessary only to punch new data cards for a new run of this same type of calculation. The control and instruction cards remain unchanged. To pick out data cards readily in a program deck, it has been found desirable to use white cards with the upper right corner cut for data cards, and colored cards with the upper left corner cut for control and instruction cards.

There are over 500 different program decks on file at the Pittsfield CPC installation at present. These decks are used for all types of engineering design and developmental and statistical calculations. Practically all of the design decks use the 5-digit general purpose plugboard system described in this paper.

Conclusions

1. The card-programmed calculator is a plugboard-type of digital computer which may be optimized for a particular kind of application.

2. A 5-digit general-purpose floating-decimal plugboard system has been successfully developed.

3. This system may be used for any calculations where slide-rule accuracy is sufficient and it has been found to be excellent for engineering design calculations.

4. The system is easy to program for and easy to check out.

5. The capacity of the CPC has been increased substantially by the use of this system. The memory has been effectively doubled and the computing speed increased by 60 per cent with no increase in machine rental fees.

Note on the Approximation Problem

NORMAN BALABANIAN
NONMEMBER AIEE

NETWORK synthesis is the aggregate of concepts and procedures utilized in obtaining an electric network whose performance approximates an arbitrarily prescribed performance. The performance specified may be the desired time response to a given excitation, such as a step or impulse function. More usually, it is the magnitude of the steady-state transfer function over all or part of the frequency axis; or it may be the angle of this function specified over all or part of the frequency axis, or it may be some combination of these over parts of the frequency axis. This paper is concerned only with a magnitude function prescribed over part or all of the frequency axis. The network functions of interest are output over input functions, with any combination of voltage or current as output and input. All of these are functions having similar properties. To include them all in the discussion the transfer function F will be defined as a function specifying the output of a network divided by the input.

In general, the network performance only approximates the specified performance because an arbitrarily specified function may not be exactly realizable by an electric network. Thus, the work involved in network synthesis may be divided into two parts:

1. Obtaining a function which approximates the prescribed function to within prescribed tolerances while at the same time being realizable as a network transfer function.
2. Obtaining a network that realizes the function found in the first part.

This paper is concerned with the first part of the synthesis problem.

A prescribed function can be approximated in one of several ways. Three useful types of approximation are:

1. Least mean square approximation. Here, the approximating function is such that the average value of the square of the error between the two functions is a minimum.
2. Taylor approximation. In this type the Taylor series of the prescribed and approximating functions are equal term by term up to a designated power. This yields a so-called maximally flat approximation.
3. Tchebyscheff, or equal ripple, approximation. In this type the approximating function oscillates, or ripples, about the prescribed function in such a way that the maximum deviations between the two functions are all equal.

In this paper a combination of the first two types will be considered.

Some Properties of Transfer Functions

The transfer function of a linear, lumped network is a rational function of the complex frequency, $s=\sigma+j\omega$, given by

$$F(s)=\epsilon^{\theta_e(s)+\theta_0(s)}$$
$$=K\frac{(s-s_1)(s-s_2)\ldots(s-s_q)}{(s-s_1')(s-s_2')\ldots(s-s_m')} \quad (1)$$

where $\theta_e(s)$ is an even function and $\theta_0(s)$ is an odd function of s. For a realizable transfer function the poles must lie in the left half-plane. The magnitude of $F(j\omega)$ can be obtained from the function

$$G(s)=F(s)F(-s)$$
$$=K^2\frac{(s^2-s_1^2)\ldots(s^2-s_q^2)}{(s^2-s_1'^2)\ldots(s^2-s_m'^2)} \quad (2)$$

by noting that

$$|F(j\omega)|^2=G(j\omega) \quad (3)$$

or

$$\theta_e(j\omega)=\frac{1}{2}\ln G(j\omega) \quad (4)$$

When $s=j\omega$, θ_e becomes the usual gain function.

Some of the properties of $G(s)$ are listed here.[1]

1. $G(s)$ is a rational function of s^2, real when s^2 is real, and positive when s^2 is negative.
2. Zeros and poles of $G(s)$ meet the following conditions:

   Complex zeros or poles occur in sets of four having quadrantal symmetry.

   Real zeros occur in pairs symmetrical about the origin.

   Imaginary zeros or poles occur in conjugate pairs of even multiplicity. This applies to zeros or poles at zero and infinity also.

If the zeros and poles of $G(s)$ are known, those of $F(s)$ can be found. Since $F(s)$ is analytic in the right half s-plane, the left half-plane poles of $G(s)$ are assigned to $F(s)$. If the network is designated to be of minimum-phase type, the zeros of $F(s)$ must lie in the left half-plane also. Thus, only one possible assignment of the zeros of $G(s)$ to $F(s)$ can be made. If the network is not so designated, there is a flexibility in the assignment to $F(s)$ from among the zeros of $G(s)$.

Approximation Procedure

The problem under consideration is the following: Given an arbitrary function of frequency, $\overline{G}(j\omega)$, prescribed over a band of frequencies not including $\omega=0$, which will be called the band-pass case, and which is to be the squared magnitude of a network transfer function, to find the poles and zeros of a realizable $G(s)$ so that $G(j\omega)$ approximates the prescribed function in some manner. Also of interest will be the case in which $\overline{G}(j\omega)$ is prescribed over the entire frequency axis. The function may be given either analytically or graphically.

The solution of this problem is obtained by a procedure which is similar to the work of Darlington.[2] Darlington deals essentially with a frequency band centered about $\omega=0$ (the low-pass case). His method handles prescribed gain or angle, or simultaneous gain and angle functions.

Darlington's procedure applied to a low-pass gain function (logarithm of the magnitude) is essentially as follows: The transformation

$$s=\frac{1}{2}\left(z-\frac{1}{z}\right);\ z=\epsilon^{u+jv} \quad (5)$$

which becomes $\omega=\sin v$ for $s=j\omega$, transforms the frequency band of interest to the unit circle in the z plane. This transformation is illustrated in Fig. 1. The prescribed gain function is expanded in a series of Tchebyscheff polynomials in ω. The series of Tchebyscheff polynomials in ω is also a Fourier series in v which can be written as a power series in z with positive and negative powers. Furthermore, equation 5 transforms a gain function in s to the sum of two functions in z, one of which has no singularities inside the unit circle, while the other has none outside. In terms of $G(s)$, use of equation 5 gives

$$G(s)=g(z)g\left(-\frac{1}{z}\right) \quad (6)$$

and

Vol.
Pt. 1
1956

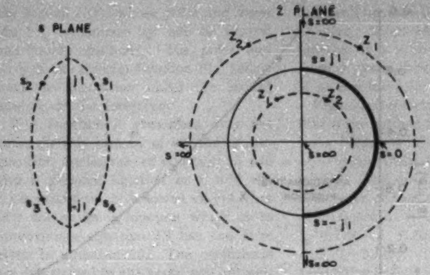

Fig. 1. Properties of the transformation $s = 1/2\,(z - 1/z)$

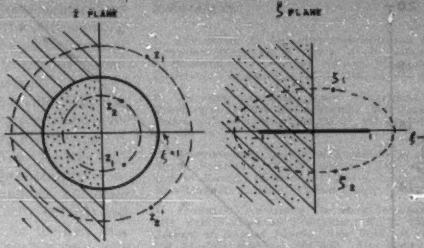

Fig. 3. Properties of the transformation $\zeta = 1/2(z + 1/z)$

$$\ln G(s) = \ln g(z) + \ln g\left(-\frac{1}{z}\right)$$

where $g(z)$ is a rational function in z with no singular points inside the unit circle. Thus, the function in z which has no singularities inside the unit circle can be approximated by a finite sum of the series in positive powers in z. This determines the poles and zeros of the gain function in the z plane and those in the complex frequency plane are obtained from equation 5.

For band-pass functions possessing geometric symmetry the same procedure can be applied by first using the band-pass to low-pass transformation

$$p = \frac{1}{2}\left(s + \frac{1}{s}\right) \qquad (7)$$

where p and s are the low-pass and band-pass variables respectively. However, if a band-pass function does not have geometric symmetry, use of equation 7 will result in a double-valued function in the low-pass plane and the procedure cannot be used.

Recently Grinich[3] has reported an interesting method extending Darlington's procedure to band-pass gain and angle functions. Kuh[4] has also dealt with the problem with the help of the potential analogy. However, both of these procedures involve elliptic functions. This paper gives a rather different method for approximating arbitrary band-pass gain or magnitude functions.

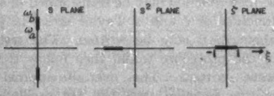

Fig. 2. The pass bands in the s, s^2, and ζ planes using the transformation $\zeta = As^2 + B$

The method is based on some simple transformations. An arbitrary band-pass function in ω can be transformed to a single valued low-pass function by the transformation

$$\zeta = As^2 + B;\ \zeta = \xi + j\eta \qquad (8)$$

where

$$A = \frac{2}{\omega_b^2 - \omega_a^2} \qquad B = \frac{\omega_b^2 + \omega_a^2}{\omega_b^2 - \omega_a^2}$$

This is illustrated in Fig. 2. The upper and lower edges of the band are ω_b and ω_a respectively. The frequency band of interest is transformed to the low-pass interval on the real axis of the ζ plane, $-1 \leq \xi \leq 1$. This interval in the ζ plane can be transformed to the unit circle in the z plane by the transformation

$$\zeta = \frac{1}{2}\left(z + \frac{1}{z}\right) \qquad (9)$$

which for real frequencies becomes

$$\zeta = \cos v \qquad (10)$$

This transformation is illustrated in Fig. 3. Note the similarities with Fig. 1. Thus, the frequency band of interest is transformed to the unit circle in the z plane.

It will be seen how equation 8 transforms a rational function of s^2 as given in equation 2 to a function of ζ. Each factor of the form $(s^2 - s_i)$ becomes $(\omega_b^2 - \omega_a^2)/2(\zeta - \zeta_i)$, so that the rational function $G(s)$ becomes

$$G''(\zeta) = K^2\left(\frac{\omega_b^2 - \omega_a^2}{2}\right)^{q-m} \frac{(\zeta - \zeta_1)\ldots(\zeta - \zeta_q)}{(\zeta - \zeta_1')\ldots(\zeta - \zeta_m')}$$

$$= \frac{1 + a_1\zeta + a_2\zeta^2 + \ldots + a_q\zeta^q}{b_0 + b_1\zeta + \ldots + b_m\zeta^m} = \frac{P_1(\zeta)}{P_2(\zeta)} \qquad (11)$$

A similar procedure can be used if the magnitude or gain function is prescribed over the entire $j\omega$ axis. The $j\omega$ axis of the s-plane is transformed to a low-pass interval by the transformation

$$s^2 = \frac{\zeta - 1}{\zeta + 1} \qquad (12)$$

The interval of interest in the ζ-plane is again the real axis from -1 to $+1$. Use of equation 9 will again transform this interval to the unit circle in the z plane. The relationship between the s and z planes can be obtained by combining equations 9 and 12. It is

$$s = \frac{z - 1}{z + 1} \qquad (13)$$

which for imaginary values of s becomes

$$\omega = \tan v/2 \qquad (14)$$

This is a well-known transformation; see Fig. 4. Perhaps its most familiar application is in the Smith chart.

Equation 12 will also transform the rational function of equation 2 into a rational function in ζ but the form will be slightly different from equation 11. Since the point at infinity in the s plane is transformed to the point $\zeta = -1$, each zero of $F(s)$ at infinity will lead to a zero of $G''(\zeta)$ at $\zeta = -1$. Thus, the rational function of equation 2 will be transformed to

$$G''(\zeta) = (\zeta + 1)^{m-q} \frac{1 + a_1\zeta + \ldots + a_q\zeta^q}{b_0 + b_1\zeta + \ldots + b_m\zeta^m} \qquad (15)$$

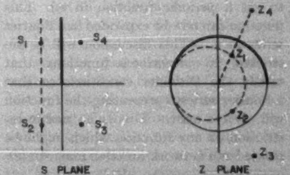

Fig. 4. Properties of the transformation $s = (z - 1)/z + 1$

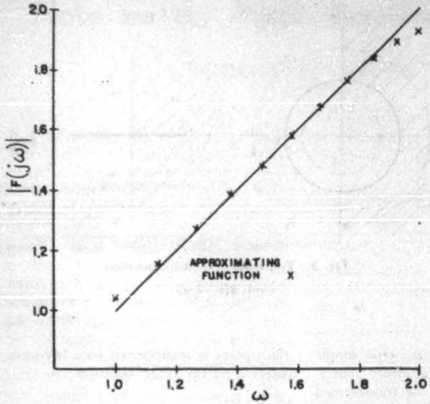

Fig. 5. Approximation of the function $|F(j\omega)|=\omega$ for $1\leq\omega\leq 2$

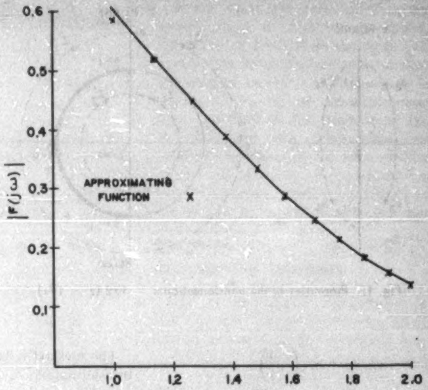

Fig. 6. Approximation of the function $|F(j\omega)|=\exp(-\omega^{2}/_{2})$ for $1\leq\omega\leq 2$

With these transformations Darlington's procedure can now be applied as described previously. However, in some cases it may not be convenient to deal with the gain (logarithm of magnitude) function. For example, it may be prescribed that the magnitude fall to zero or to a very small value at the edges of the band. In such a case, the gain will go to negative infinity or to a large negative value at the edges of the band. The Fourier series representing the gain function will then converge very slowly, if it converges at all, and a large number of terms will be needed to obtain an adequate approximation. This disadvantage can be overcome if the magnitude function is used. The problem then is that of a prescribed magnitude function either over a finite band of frequencies or over the entire $j\omega$ axis.

In this case, the approximation procedure would be as follows. If a magnitude function $\bar{G}(j\omega)$ is prescribed over a band of frequencies, use equations 8 and 10 to transform this to a periodic function of v, $\bar{G}'(v)=\bar{G}(j\omega)$. (If $\bar{G}(j\omega)$ is prescribed for all ω, use equation 14 to get a periodic function in v.) This function can now be expanded in a Fourier series in v. (This discussion will be restricted to prescribed functions that satisfy the Dirichlet conditions so that a Fourier series representing the function will always exist. This is no undue restriction on any function which might be wanted as a network function magnitude).

$$\bar{G}'(v)=\sum_{k=0}^{\infty}\bar{C}_k\cos kv \qquad (16)$$

An approximation to the prescribed function is made by retaining a finite number of terms of this series, the actual number of terms depending on the prescribed tolerance. This finite trigonometric sum is then rewritten as a trigonometric polynomial in $\cos v$ by use of the identity

$$\cos kv=2\cos(k-1)v\cos v-\cos(k-2)v \qquad (17)$$

Finally, use of equation 10 changes this to a polynomial in ζ, which may be written

$$\bar{G}''(\xi)=\sum_{k=0}^{n}d_k\xi^k \qquad (18)$$

This is an approximation to the prescribed function, suitably transformed. The objective is to have this polynomial approximately equal to the rational function of equation 11. The approximation could take one of several forms. The simplest procedure would be to make the coefficients of the Taylor series of $G''(\zeta)$ about $\zeta=0$ coincide with the coefficients in equation 18 up to the nth power for real values of ζ. This can be accomplished by writing

$$\frac{P_1(\xi)}{P_2(\xi)}=\frac{1+a_1\xi+\ldots+a_q\xi^q}{b_0+b_1\xi+\ldots+b_m\xi^m}\doteq\sum_{k=0}^{n}d_k\xi^k \qquad (19A)$$

or

$$P_1(\xi)\doteq P_2(\xi)\sum_{k=0}^{n}d_k\xi^k \qquad (19B)$$

To determine the coefficients, first multiply the right-hand side out. The left-hand side is of degree q. Hence, coefficients of ξ of degree $(q+1)$ to $(q+m)$ on the right-hand side are equated to zero. This gives a set of m simultaneous linear equations in the b coefficients. After this set is solved and the b coefficients determined, the a's are determined by equating coefficients of like powers of ξ from zero to q on both sides of equation 19. To solve for all the coefficients uniquely, n must equal $m+q$. The coefficients are easiest to determine when all the zeros of the rational function $G''(\zeta)$ are at infinity; then $P_1(\zeta)=1$. In this case there is no need to solve simultaneous equations.

There are two approximations involved in the over-all procedure. One is a least mean square type, when a finite number of terms is retained in the Fourier series. The second is a Taylor type, when the coefficients of the rational function are determined. The combination seems to give an approximation which is almost Tchebyscheff, and this has been called quasi-Tchebyscheff or nearly-equal-ripple.

The procedure can be modified to obtain a different type of approximation. Instead of transforming the prescribed function of ω to a function of v and then obtaining the Fourier series, the prescribed function may be transformed to a function of ξ and a Taylor series in ξ about $\xi=0$ may be written. The rest of the procedure would then follow the same pattern. The over-all approximating function then will not oscillate about the prescribed function.

After the coefficients of $G''(\zeta)$ are determined, use of equation 8 will give the desired $G(s)$, whose poles and zeros can be determined by one of several root-finding methods. The poles and zeros of the transfer function $F(s)$ follow from the discussion under the second heading in the foregoing.

If a function is prescribed over the entire $j\omega$ axis instead of a band of frequencies, application of equation 14 will give a periodic function in v, and the same procedure is followed except that now the rational function which is to approximate equation 18 has the form given in equation 15. The coefficients are determined in the same way but now there will be more simultaneous equations to solve. Even when the corresponding function in s is to have all its zeros at infinity, we will need to solve a system of m simultaneous equations.

Figs. 5 and 6 show the results of application of the method to the prescribed functions $|F(j\omega)| = |\omega|$ and $|F(j\omega)| = \exp(-\omega^2/2)$ respectively, both in the range $1 \leq |\omega| \leq 2$. The zeros of both transfer functions were chosen at infinity. The poles of $F(s)$ are at $(-0.34055 \pm j2.1502)$ and $(-0.77816 \pm j1.5272)$ for the first case and (-2.147), $(-0.561 \pm j0.888)$ and $(-0.801 \pm j1.702)$ for the second.

Conversion of Studio Lighting from Black and White to Color Television

P. W. WYGANT
NONMEMBER AIEE

THIS is the story of the conversion from black and white to color television (TV) lighting at Station WBAP-TV in Fort Worth, Tex. Some problems of such a conversion will be unique at each different station. For example: the problems of integrating a new lighting system with the old installation, the type of programming anticipated, the personnel available and, of course, the ever-varying budget. This paper presents the needs of the station and describes how they were met. First, however, the lighting facilities on hand before the addition of color equipment will be outlined.

Original Equipment

The studio to be converted was constructed in the summer of 1948; see Fig. 1. The studio is 82 feet long, 45 feet wide, and 28 feet high. A pipe grid is mounted 20 feet above the floor and is constructed of $1^1/_4$-inch galvanized pipe arranged in 7-foot squares suspended from the ceiling. A 3-foot catwalk runs around the two sides and the end of the studio, 14 feet above the floor.

The lighting fixtures and control equipment in use just before the conversion to color were essentially those purchased and installed in 1948. There were 18 Television Associates banks of incandescent lamps: see Fig. 2. Each fixture contained 12 lamps of which six were type-*PAR-38* floods, and six were type-*R-40* floods. Separate circuits were used to supply power to the two types of flood lamps. The *PAR*-type lamps were used for modeling, while the *R-40* type of lamp was used for fill light. Each fixture was designed to permit adjustment in azimuth and elevation. A 360-degree turn plus tilt adjustments were made by means of cords running to a central location. Similar turn-and-tilt adjustments were provided for 15 fluorescent fixtures, which each contained six 64-inch slimline tubes. Back light was provided by fresnel spots which were mounted on the catwalk rail. Ten 2-kw spots and 10 750-watt spots were in use.

The total wattage from all fixtures amounted to 62 kw, or approximately 18.5 watts per square foot. In 1948 and 1949 it was the practice of the station to provide 200 foot-candles for use with the 5655-image orthicon tubes. With the fixtures then available it was not possible to provide 200 foot-candles around the four walls of the studio. However, by means of the turn-and-tilt controls, it was possible to concentrate the light on any two or three areas in use at any one time. Later, with the development of the more sensitive 5820-image orthicon pickup tube, only 100 foot-candle studio lighting was required. A 100-foot-candle illumination could be provided uniformly for any area in the studio without turning fixtures.

Original Lighting Switchboard

The switchboard was designed to handle 140 separate circuits. One hundred forty silent-type mercury switches were used to remote-control a similar number of relay contactors. Each switch was rated at 10 amperes while the load contactors handled the load current of 20 amperes. One relay load contactor was used for each load receptacle. Each load circuit was provided with a 20-ampere circuit breaker. The load contactors were fed from two 200-ampere main breakers in the power feed.

With the advent of the 5820-type image orthicon tube there was a lessening of the infrared problem noticeable with the earlier types of pickup tubes. At this stage a dimmer board of 12-kw capacity was constructed and placed into operation. It was used only by those desiring very special lighting effects since its operation necessitated the running of extension cables along the grid from the dimmer to the fixture. Therefore, a great deal of ladder work was required for dimmer effects. In fact, the main objection to the control switchboard by the operating personnel was its position on the catwalk 14 feet above the studio floor. The load contactors were subject to sticking, thus leaving the circuit continually hot until someone filed or replaced the contact points. Fig. 3 shows the location of the original switchboard on the catwalk.

If the system described in the fore-

Paper 56-76, recommended by the AIEE Television and Aural Broadcasting Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. P. W. Wygant is with Station WBAP, Fort Worth, Tex.

Fig. 1. WBAP-TV studio showing original lighting equipment

going appears cumbersome and inflexible (and it was) note that it was designed in 1947 when there was very little information available on the subject. Briefly, then, this was the situation early in 1954 before the station started adding lighting equipment in preparation for live color originations.

Air Conditioning

As is well known, the summers of Texas are not mild. One of the first problems at Station WBAP-TV was the disposal of the additional heat to be generated by the increased lighting load. A heat exchanger was built on the roof of an adjoining building with connecting ducts feeding into the end of the studio. Two 100-ton compressor units were already in use. One 60-ton compressor unit was added to the existing chilled water lines which were extended to the new heat exhaust. Additional ducts were added above the grid in the studio. The new studio air-conditioning capacity was almost doubled over that of the existing installation.

Primary Power

The substation in use in 1954 belonged to the Texas Electric Service Company and had a 450-kva capacity. The three transformers in use were purchased from the service company. Three similar 150-kva transformers were added to the transformer bank to give a total of 900-kva installed capacity. The total load was not expected to be doubled, but it was felt that the reserve power capacity would suffice for possible future needs. When the new transformers were installed, the complete substation was purchased from the service company. It appeared to be an economical move to purchase the substation since the saving in power costs would pay for the transformers within approximately 6 years.

In the basement power vault a new 150-kva transformer was added to the secondary bus. Fortunately there was space to fit the new transformer in the same room with two similar 150-kva transformers already in use. The new transformer feeds 120 to 208-volt 3-phase 4-wire service to a 400-ampere main circuit breaker. The second transformer feeds two 200-ampere breakers, one of which is the main for lighting in another TV studio.

The Texas Electric Service Company furnishes primary power on its lines to the property line where it is metered at a common point. Then by WBAP lines primary power is sent to the transmitter building for air conditioning and transmitter power. From the substation at the main building, service is provided to the air-conditioning compressors, heat exchangers, motors, and equipment requiring 440-volt service. The secondary bus feeds a 50-kva transformer serving the building and film-laboratory needs; a 100-kva transformer for radio studio equipment; a 150-kva transformer for regulated power to the TV equipment; a 150-kva transformer serving a 200-ampere main circuit breaker to studio No. 2 lighting; and a 200-ampere main breaker to studio No. 1 dimmer circuit. There are 12 50-ampere subbreakers on this circuit. The last 150-kva transformer on the secondary bus feeds the 120- to 208-volt 3-phase 4-wire service to the nondim circuit on the switchboard in studio No. 1. There are, of course, many other circuits fed from the secondary bus transformers, for instance, a circuit to provide power to the remote

Fig. 2. View from catwalk: original lighting equipment

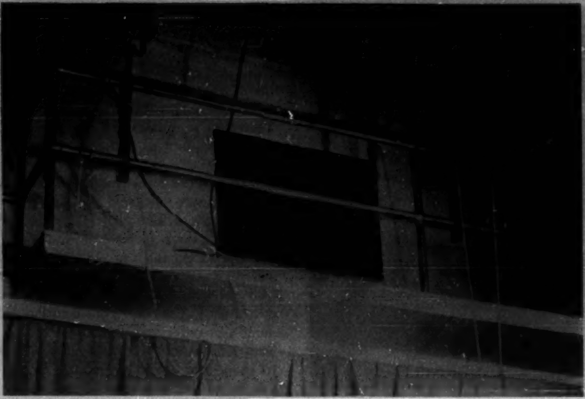

Fig. 3. Original switchboard

truck for adjusting equipment while the truck is parked in the garage.

New Lighting Switchboard

The new studio switchboard has a capacity of 1,800 amperes. The nondim circuit contains 400-ampere main fuses and a main switch. There are 12 100-ampere subbreakers. The dim circuit contains 200-ampere main fuses and a main switch. There are 12 50-ampere subbreakers each feeding a 5.5-kw Ward Leonard autrastat dimmer. Master and submaster dimmer control handles are provided.

Rotolector switches are used in the new switchboard. They are a convenient means of crossconnecting a load circuit to any supply circuit. Twenty-four-point rotolectors are used, corresponding to the 24 subcircuits, 12 dim and 12 nondim. In all, there are 140 20-ampere and 10 50-ampere units, each with a circuit breaker and pilot light. Twelve ammeters across the top meter the dimmer circuits to allow the operator to load the dimmers to their full capacity. The switchboard and rotolectors are on a platform elevated 3 feet above the studio floor. The valuable studio floor space lost is offset by the convenience of a nearby location; see Fig. 4. A tremendous saving in power has been realized from this new location. With the new lighting load it would be a very great waste to have lamps burning that were not essential. The new switchboard location makes it practical to keep the lights off unless in actual use. The turn-and-tilt controls were moved along with the switching to the platform.

Load Circuits

Under the old system the load circuits were fed from the relay contactors into the studio in 4-inch-square ducts with hinged covers. There was a total of 120 twist-lock receptacles in connecting boxes. Fortunately, there was plenty of space in these ducts to accommodate additional wiring. The load wire to each receptacle was disconnected from its relay terminal, lengthened, and connected to its proper rotolector terminal, thus utilizing most of the existing wiring and all of the existing receptacles. Under the old system a separate neutral wire was connected to three receptacles. It was necessary to add neutrals so that the neutral of each receptacle was individually fed back to the rotolector board. Twenty additional 20-ampere twist-lock and 10 50-ampere pin-type receptacles were added to these ducts above the grid.

New Fixtures

The 18 Television Associates incandescent banks in use since 1948 were retained. These continued to use both the *PAR-38* and *R-40* types of lamps on separate circuits, and retained their turn-and-tilt controls. The 15 slim-line fluorescent fixtures were taken down, not because of any adverse experience with the light quality, but because of their physical size and space limitations; see Fig. 5. Fifty 18-inch scoops were added, each using 2-kw clear *PS-52* general service lamps. Eighteen scoops were hung on individual pantagraphs. To make it possible to lower these scoops to eye level the pantagraphs were installed on a 1-inch pipe grid suspended 3 feet below the permanent grid. The remaining 32 scoops were hung on pendant clamps with a 4-foot height adjustment. These in turn were hung in pairs from turning spindles similar to the turning devices on the Television Associates telelights. These we made up from spare parts and 3/4-inch pipe. Thirty 8-inch fresnel spots were added for back and key lighting. Two-kw

Fig. 4. New switchboard; dimmers at left, rotolector switches at right

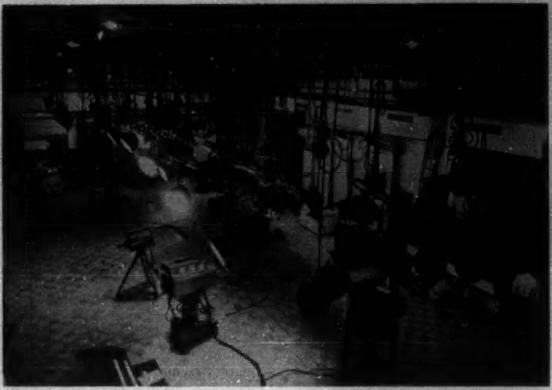

Fig. 5. New lighting layout. Note switchboard at right

G-48 mogul bipost lamps are being used in these spots. For effect use, five 16-inch fresnel spots using 5-kw mogul bipost lamps were added; for similar use, six 6-inch strips each containing 12 150-watt *R-40* spot lamps; two 750-watt boom lights; and two 8-inch 2-kw pattern projectors. There are now 60 watts per square foot as compared with 18.5 previously used; see Fig. 6.

Briefly, the considerations which prompted the types and number of fixtures, the control equipment, and the method of installation are these: First, the station was in no position to scrap its investment in the Telelight incandescent 12-lamp banks. Although these fixtures are old and the light output not as controllable as sometimes might be desired, they do provide a large quantity of light, which is one of the essentials for lighting a color set. Therefore, the first consideration was the integration of the incandescent fixtures, at least, if not the fluorescent fixtures, with the new lighting system. The second consideration was the programming. It was planned to start from the first with $5^1/_2$ hours per week of live studio programs. This made it advisable to provide one end and one side of the studio with 400 foot-candles of light at any one time. Further it was desirable to be able to swing the light quickly from one side of the studio to the other during a program. As an example of actual practice: If scene 1 is along the west wall and scene 2 is on the air from the south end of the studio, the lights can be readjusted by one man from the west side over to scene 3 along the east wall. This leads to the third consideration, that no additional personnel would be added to the staff to take care of the lighting. One man is responsible for the lighting and for lighting equipment maintenance. He has other duties, but before and during the color shows he devotes his entire time to lighting. This is the reason as many fixtures as possible have turn-and-tilt adjustments controllable from a central location. The next consideration involves accurate intensity control. It was desired to light all sets with a uniform light level of 400 foot-candles plus or minus no more than 25 foot-candles. Lighting effects, particularly those involving dimming, have always been important to the station and it was desired to continue or even expand the use of effects. Therefore, to make the lighting as uniform as possible, as well as to make possible any effects the directors might like to try, the rotolector board and the dimmers were included in the plans. In any case, a new control system was necessary, since it was physically impossible to expand the old switchboard and relay system to carry the additional load, even if the old system had been continued. The last consideration, in numerical order only, was the budget. The management was, of course, willing to spend the amount necessary to provide a good color picture. Some effects qualified, but large numbers of elaborate devices and accessories did not.

There are always new products on the market, or changes, or expansions to plan for and this station, like other TV stations, is continually ready for improvements. As soon as funds are available, plans call for conversion of another studio 30 by 40 feet, from black and white to color, additional spots for use as back light in the large studio, and possibly later conversion to pin-type cable connectors.

It is not the intention of this paper to imply that the setup described is ideal, but after nearly 2 years of color operation it has proved itself very practical for the type of operation in this studio.

The Operation of the Self-Balancing Magnetic Amplifier

ALBERT D. KRALL
NONMEMBER AIEE

EDWARD T. HOOPER
ASSOCIATE MEMBER AIEE

FEEDBACK has been applied to amplifiers almost since their inception to alter the gain, bandwidth, impedances, etc. A combination of positive and negative feedbacks, decoupled from each other was applied to a vacuum-tube voltmeter by Gilbert.[1] Geyger has reported on[2] and patented[3] a magnetic circuit similar in operation to the Gilbert circuit which has been designated the self-balancing magnetic amplifier. This amplifier has appeared in many forms. Voltage and current types, both single-ended and push-pull, are possible configurations. These amplifiers have been shown, experimentally, to have large power gains, linear output-input characteristics, and a high speed of response. Scorgie[4] in comparing the self-balancing-type magnetic amplifier with the half-wave amplifier of Ramey has analyzed this circuit and reported that the speed of response can be made one half-cycle of the power supply frequency.

The purpose of this paper is two fold: first, to set forth the principle of self-balancing amplifiers; and, second, to clarify the operation of the self-balancing magnetic amplifier by means of detailed description and analysis. Since the magnetic amplifier operates on a basis of average output as a function of average input, a method of analysis will be employed that utilizes this characteristic. This particular method has been introduced to the magnetic amplifier art by Johannessen.[5]

Self-Balancing Amplifier Concept

To introduce the principle of the self-balancing amplifier, the block diagram shown in Fig. 1 will be discussed. It is not intended that the blocks represent individual parts of the self-balancing magnetic amplifier. The over-all characteristics of the block diagram are inferred to be the properties of an ideal self-balancing amplifier of any type.

A signal S is applied to the real input. It proceeds to the output after having been amplified to a value of kS. At the output there are two feedback loops. Considering first the lower or negative feedback loop, the output kS is attenuated to its original value of S and applied negatively to the real input. Thus, at the real input the originally applied signal S is completely balanced or negated. Simultaneously the upper or positive feedback loop applies a positive signal of value S to the apparent input. Isolation between the feedbacks is necessary to prevent their interaction or cancellation. The circuit is now stabilized with a finite output and zero input power. The signal source was required to supply power only during the transient. For this reason it is important to have an amplifier possessing fast response. There are four properties of this analogy which will be considered the fundamental requisites of self-balancing operation. First, the input power is zero after the initial transient; second, the output power is finite; third the signal gain is k; fourth, the response must be rapid to minimize transient power drain from the input. The first and second properties lead to a power gain approaching infinity. It must be noted that infinite power gain is a result of zero input power and not a result of high signal gain.

No restriction was made on the nature of the signal S. The self-balancing principle can be applied to balance either a current signal or a voltage signal. When a voltage input signal is balanced by feedback there results zero input current and a finite voltage gain, k. When a current input signal is balanced by feedback, there results zero input voltage drop and a finite current gain, k. It will be shown that the so-called self-balancing magnetic amplifier fulfills these requirements.

Circuit Operation

From the various types and combinations, the single-ended voltage-type self-balancing magnetic amplifier has been chosen for discussion. Assume first the familiar magnetic amplifier circuit shown in Fig. 2. This is the series-connected saturable reactor with external feedback. From this circuit the self-balancing magnetic amplifier will be evolved. As this circuit has been analyzed and discussed at length in the literature, no attempt will be made here to explain its complete operation. In general, the assumptions are made of ideal rectifiers and square-loop core material having no magnetizing current. With these assumptions Johannessen derives the following equation for the circuit of Fig. 2 where $N_F = N_L$.

$$E_0(n+1)=\frac{N_L+N_F}{N_C}E_c(n)+E_0(n)$$

The terms $E_0(n)$ and $E_0(n+1)$ are the respective average output voltages for nth and $(n+1)$th half-cycles of e_s and $E_c(n)$ is the average control voltage for the nth half-cycle. Note that the output on the $(n+1)$th half-cycle is a function of the output on the nth half-cycle. Thus a feedback is involved. The equation shows that the amplifier is unstable because the coefficient of the feedback factor $E_0(n)$ is unity. Unity feedback in this case is sometimes referred to as 100-percent postive magnetic feedback. It can also be seen from the equation that, since $E_0(n+1)$ never reaches its theoretical final value, the theoretical time constant is infinite. In a practical case the amplifier will saturate at some point and yield a finite output and time constant.

Before self-balancing can be attempted, the time constant must be reduced. This is accomplished by negating the positive feedback signal in the control circuit by the introduction of a negative electric feedback.[6] Into the circuit of Fig. 2 has been added a resistance R_K, as shown in Fig. 3. R_K is electrically common to the output and the control circuits and is the element responsible for the negative electric feedback.

The circuit of Fig. 3 will be analyzed to show the effect of R_K on the time constant and gain and to show the presence of some of the properties of an ideal self-balancing amplifier. The discussion is supplemented by the more rigorous mathematical analysis contained in Appendix I.

The basic assumptions for this analysis and discussion are as follows. The core material is considered to have a rectangular hysteresis loop, with a finite ampere-turn coercive and volt-time integration required to change flux on the loop. Ideal rectifiers have been assumed. Throughout the discussion the windings N_L are equal to the windings N_F. There are two basic modes of operation. Mode 1 is defined when both cores are unsaturated and mode 2 is defined when one core

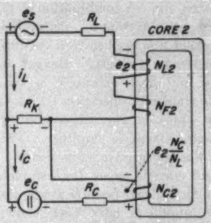

Fig. 5. Equivalent circuit of Fig. 3 for mode 2 of the nth half-cycle

is saturated and the other is unsaturated. These are the only modes permitted for proper operation. For any given half-cycle of the supply voltage e_s, one core will remain unsaturated, integrate a voltage, and flux will be set into it. The other core will have had flux set into it on the previous half-cycle; it will integrate a voltage, change the flux, and allow the core to saturate. Upon the following half-cycle the circuitry will reverse the roles previously performed by each core. For this reason only one-half cycle of operation will be analyzed; the other will be implied. Assume the source voltage e_s is of the polarity noted in Fig. 3. This particular half-cycle will be called the *n*th half-cycle. For the *n*th half-cycle the basic circuit has been redrawn, excluding the rectifier symbols, in Fig. 4. (The equivalent circuit for mode 2 is shown in Fig. 5.) Both cores start the half-cycle unsaturated. As the power supply e_s drives magnetizing current around the circuit, a voltage appears across the core windings. In core *1* the fluxes from N_F and N_L are additive; in core *2* they negate. Since N_F equals N_L, the only winding effective on core *2* is N_C. As long as core *2* remains unsaturated, the control current will be limited to the magnetizing current of N_C of core *2*. Magnetizing current will flow in the power circuit limited by core *1* and the voltage drops across the relatively low valued resistors R_L and R_K are considered negligible in comparison with other voltages in the power circuit. The voltage across N_{L1} is induced into N_{C1} of the control circuit. This induced voltage is in the order of magnitude of the supply voltage when N_L and N_C are of the same order and its polarity is shown in Fig. 4. The equation for the voltages summed around the control circuit is

$$e_1\frac{N_C}{N_L}=i_c(R_C+R_K)-i_LR_K+e_c+e_2\frac{N_C}{N_L}$$

At quiescent conditions ($e_c=0$) almost all of the induced voltage (e_1N_C/N_L) is dropped by the impedance of N_{C2}, since the resistors R_K and R_C are small in comparison to the impedance of N_{C2}. This voltage e_2N_C/N_L that is impressed on N_{C2} from N_{C1} causes a flux to be set in core *2*. Note that e_2N_C/N_L is not induced from N_{L2} because, as it was previously mentioned, the fluxes on the windings N_{L2} and N_{F2} negate each other. Depending on previous history, core *1* will or will not saturate during the *n*th half-cycle. If quiescent conditions had existed, core *1* will not saturate. Consequently, for the full *n*th half-cycle N_{C2} has a voltage impressed on it and enough flux will be set to keep core 2 from saturating on the (n+1)th half-cycle. If, however, a signal e_c exists of the polarity shown, core *1* will saturate. At the saturation of core *1* the induced voltage (e_1N_C/N_L) will drop to zero and the equation of the control circuit becomes

$$i_LR_K=i_c(R_C+R_K)+e_c+e_2\frac{N_C}{N_L}$$

Saturation of core *1* allows the load current i_L, which had previously been small, to assume a value equal to $e_s/(R_L+R_K)$. Thus in the control circuit as the induced voltage e_1N_C/N_L goes to zero, another voltage across R_K replaces it. When the value of R_K is adjusted so that the ratio $\dfrac{N_F+N_L}{N_C}$ equals the ratio $\dfrac{R_L+R_K}{R_K}$, the voltage drop across R_K exactly replaces the induced voltage e_1N_C/N_L that would have appeared across N_{C1} at quiescent conditions. The effect of this adjustment is to cause a constant voltage to appear across the combined components N_{C1} and R_K no matter what the saturation point of core *1* may be.

This constant average voltage, hereafter known as V_c, is opposed by the average control signal E_c and the net voltage V_c-E_c appears as e_2N_C/N_L across N_{C2} to set flux in core *2*. When E_c approaches V_c, a reduced amount of flux is set into core *2*. As a result of this core *2* saturates earlier in the (n+1)th half-cycle and more average load current flows. Thus, as the control signal increases from zero, the load current increased from magnetizing current. When E_c equals V_c no flux is set in core *2* and full output will occur on the (n+1)th half-cycle. Equation 19 describes the operation of the circuit.

$$E_0(n+1)=\left[\frac{N_L+N_F}{N_C}\,\frac{R_L}{R_L+R_K}\right]E_c(n)+\left[1-\frac{N_L+N_F}{N_C}\,\frac{R_K}{R_L+R_K}\right]E_0(n)$$

This equation and the equation of the series-type saturable reactor with external feedback are of the same form. The addition of R_K to the circuit has changed the coefficients of the terms. The reduction of R_K to zero in equation 19 reproduces exactly Johannessen's equation for the series-connected saturate reactor with external feedback.

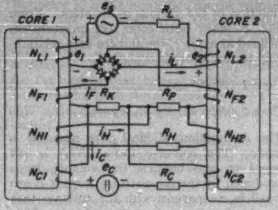

Fig. 6. Basic amplifier with negative electric feedback and "boosting" circuit

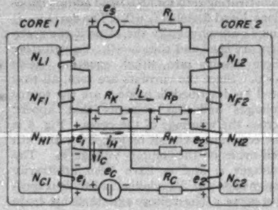

Fig. 7. Equivalent circuit of Fig. 6 for mode 1 of the nth half-cycle

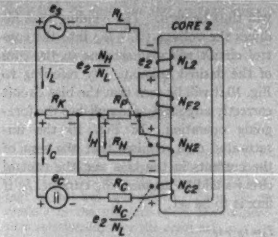

Fig. 8. Equivalent circuit of Fig. 6 for mode 2 of the nth half-cycle

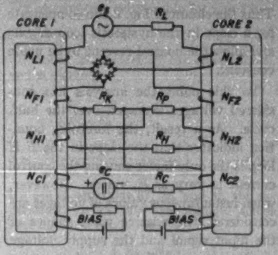

Fig. 9. Basic amplifier with negative electric feedback, "boosting" circuit, and bias

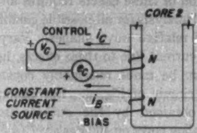

Fig. 10. Combined control and bias operation

The adjustment of the ratios $\frac{N_L+N_F}{N_C}=\frac{R_L+R_K}{R_K}$ to provide a constant V_e, as discussed previously, reduces equation 19 to

$$E_o(n+1)=\frac{R_L}{R_K}E_c(n)+[0]E_o(n)$$

This equation states that the average output voltage on the $(n+1)$th half-cycle is only a function of the average control voltage of the nth half-cycle. Thus the time constant or delay has been reduced to one half-cycle. The voltage gain has been reduced from infinity to a value equal to R_L/R_K. An increase in voltage gain greater than R_L/R_K can be obtained but only at the expense of the speed of response. To this point it has been shown that the circuit of Fig. 3 has three of the characteristics of an ideal self-balancing amplifier. It has a fast response, a finite output power, and a finite signal gain.

The fourth characteristic, that of zero input power, is so far present only if magnetizing current in the control circuit is neglected. However, for many applications the input current is required to be much lower than magnetizing current.

Before proceeding, a brief résumé of what has been done will be made. To the series-connected saturable reactor with external feedback a resistor R_K has been added to provide negative electric feedback. By making the appropriate adjustment of R_K the amplifier voltage gain is represented by a resistance ratio which in turn is equivalent to the turns ratio from the input to the output. The voltage gain here considers the output voltage as being not just composed of the voltage across R_L but of the voltage developed across the total resistance (R_L+R_K) of the output circuit. In other words, at half-cycle response the voltage amplification is the same as that of a simple transformer. As there is no feedback term present in the resulting equation, the amplifier has a gain K if the half-cycle dead time is neglected. That is, even though the "100-per-cent positive magnetic feedback" and "100-per-cent negative electric feedback" may be present, their effects cancel, resulting in no apparent feedback.

It was stated that there is always one unsaturated uncoupled winding in the control circuit. A voltage appears across this winding because of the unbalanced voltage sources in the control loop. The integral of this voltage produces a flux resetting the core. Because of the nature of an unsaturated core, only magnetizing current is allowed to flow through the control winding no matter how large the voltage across the winding is. Now it would be advantageous to reduce the magnetizing current to zero in the control circuit because that would mean zero input power.

If the control current is constant at magnetizing current or less with a changing e_c, a bias circuit, consisting of a current source on an additional winding, is sufficient to reduce the control current current to zero, since the current will then be supplied by the constant current source instead of the control circuit.

In practice when I_c is not constant with changing e_c, a circuit that resembles the conventional boosting circuit is used to produce a constant I_c. This "boosting" circuit is added to Fig. 3 to produce the circuit of Fig. 6. This circuit is analyzed in Appendix II (see Figs. 7 and 8) and the defining equation is

$$E_o(n+1)=\frac{N_L+N_F}{N_C}\frac{R_L}{R_L+R_K+R_P}E_c(n)+\left[1-\frac{N_L+N_F}{N_C}\frac{R_K}{R_L+R_K+R_P}\right]E_o(n)$$

To eliminate the feedback term in the defining equation $(N_L+N_F)/N_C$ is required to equal $(R_L+R_K+R_P)/R_K$ and whereupon the defining equation becomes

$$E_o(n+1)=\frac{R_L}{R_K}E_c(n)$$

Note that the adjustment of the ratios now accounts for the effect of the added circuit by including R_P. The circuit of Fig. 6, when the "boosting" circuit is properly adjusted, now has the same voltage gain and response time as the circuit of Fig. 3.

To make the control current constant in the circuit of Fig. 6, the derivative of the control circuit current with respect to the control voltage was equated to zero in Appendix III. The condition to be met is that

$$(R_K+R_P)\frac{di_L}{de_c}+\frac{N_L}{N_C}(R_H+R_P)\frac{dI_o}{de_c}=1$$

When this equation is satisfied, the control circuit current will be constant and can be again shifted to zero by the addition of a bias circuit. The term di_L/de_c for half-cycle response is constrained to equal $1/R_K$ since

$$R_L\frac{di_L}{de_C}=\frac{dE_o}{de_c}=\frac{R_L}{R_K}$$

Thus the circuit of Fig. 6 can compensate for a slope in the hysteresis loop dI_0/de_c and allow the control current to be made constant.

To this point the analysis has considered voltages averaged over the half-cycle. As a result, the foregoing equation indicates that the slope in the *B-H* loop is the only factor causing the control current to vary as E_c varies. However, when instantaneous values of voltages are considered, the relative wave shapes of the input signal and the supply voltage can have a great effect upon the average current flowing in the control circuit. A discussion of these effects requires an individual analysis for all possible combinations of relative wave shapes. Varying control current due to these effects, however, can be made reasonably constant by the circuit of Fig. 6. For example, values obtained by the authors using supermalloy cores on 400 cps are I_c(d-c) = ±1.5 microamperes for a control voltage range of 0.5 to 10 volts supplied by pure d-c source.

The fourth requisite for self-balancing i.e. zero input power, has now been achieved in the voltage-type amplifier shown in Fig. 9 by reducing the control current to zero for a range of control voltages. It was necessary to perform two operations simultaneously to achieve zero input current and still control the amplifier. The bias circuit performs these two operations but before showing the effects of the bias circuit in Fig. 10, the normal operation of the control circuit will be reviewed. In the control circuit there exists two voltage sources, the constant voltage V_c and the varying input signal E_c. The difference between these two voltage sources (V_c-E_c) appears across the control winding and is integrated, according to Faraday's law. The flux produced by the voltage integration varies with the input voltage and is necessary for proper operation of the amplifier. When (V_c-E_c) is applied to the control winding, the magnetic core material, assumed to have a rectangular loop, allows only magnetizing current to flow through the control winding. Magnetizing current is of constant magnitude, i.e., independent of the magnitude of (V_c-E_c). Thus as E_c varies from zero and approaches V_c, the current i_c is constant and has a value of magnetizing current I_0.

It is desirable to reduce i_c to zero but have the flux set into the core remain the same. One way to reduce i_c to zero is to induce a voltage into the control winding whose magnitude is (V_c-E_c). If this is possible, all of the voltage sources in the control circuit will sum to zero and i_c will thus be zero. The winding that induces the voltage (V_c-E_c) into the control circuit will also set flux in the core of the desired amount. By referring to Fig. 10 it will be seen that the bias circuit correctly adjusted, accomplishes the foregoing operation. In Fig. 10 the unsaturated core requires that the sum of the currents in the bias and the control circuits add to magnetizing current, I_0, if flux is to be set.

$$I_0=i_B+i_c$$

By adjusting the constant current source to produce i_B equal to I_0, the core requirements are then satisfied if i_c equals zero. Due to the nature of a constant current source adjusted to supply $i_B=I_0$, any voltage necessary to accomplish this will automatically be supplied across the bias winding. The voltage necessary to allow $i_B=I_0$ is exactly (V_c-E_c) and (V_c-E_c) will appear across the bias winding. From there it is transformed into the control winding summing all of the control voltage sources to zero and thus i_c becomes zero. The voltage (V_c-E_c) across the bias winding is also integrated, supplying the flux to the core necessary for the proper over-all circuit operation.

In practice i_c will approach zero depending on how well the "boosting" circuit can make i_c constant with E_c and on how near to ideal a constant current source is available.

With reference to the block diagram of Fig. 1, the negative feedback loop can be identified with the action of the bias circuit in reducing control current to zero. The simultaneous action of the bias circuit in setting the flux in the unsaturated core can be identified with the positive feedback into the apparent input.

Conclusion

Self-balancing amplifiers can operate from zero input power, exclusive of the transient input power, and deliver finite output power. A finite signal gain (either voltage or current) is obtained.

The self-balancing magnetic amplifier is shown to possess these properties with a speed of response that can easily be made one half-cycle of the power frequency.

The action of the "boosting" and bias circuits in relation to the self-balancing operation has been explained.

Appendix I

Fig. 3 is the diagram of the amplifier to be analyzed. The analysis will follow closely the method of Johannessen. The mathematical expressions are directed toward writing the average output voltage as a function of the various parameters. From Fig. 3, when both cores are unsaturated, defined as mode 1, the ampere-turn relationship for each core is expressed.

$$\text{Core } \mathit{1}\ (NI_0)=i_LN_L+i_FN_F-i_cN_c \tag{1}$$

$$\text{Core } \mathit{2}\ (NI_0)=i_LN_L-i_FN_F+i_cN_c \tag{2}$$

The assumption of ideal core material is made. The coercive force (NI_0) is set equal to zero because the voltage drops produced by the magnetizing current I_0 are small in comparison with the voltages that appear in the rest of the circuit. This condition implies not only that I_0 is small but that R_K, R_L, and R_C be relatively small. Substituting zero for (NI_0) and adding equations 1 and 2 yields $i_L=0$. The currents i_L and i_F are physically the same if the rectifiers are ideal and thus $i_F=0$. Substituting these results into either equation yields $i_c=0$. Since the currents are zero, all that need be described in mode 1 are the source voltages and the voltages that appear across the windings of the cores. Fig. 4 is the equivalent circuit of Fig. 3 for the *n*th half-cycle of the supply voltage e_s. The voltages e_1 and e_2 have been arbitrarily assigned to the N_L windings of their respective cores. The voltage equations for mode 1 of Fig. 4 are

$$e_s=e_1+\frac{N_F}{N_L}e_1-\frac{N_F}{N_L}e_2+e_2 \tag{3}$$

$$e_c=\frac{N_C}{N_L}e_1-\frac{N_C}{N_L}e_2 \tag{4}$$

For this analysis N_F is always equal to N_L. Substituting this condition and solving equations 3 and 4 for e_1 and e_2 yields

$$e_1=\frac{e_s}{2} \tag{5}$$

$$e_2=\frac{e_s}{2}-\frac{N_L}{N_C}e_c \tag{6}$$

Equations 5 and 6 give the voltages across the N_L windings of the reactors for mode 1 of the *n*th half-cycle. The action of the rectifier bridge will interchange the values of e_1 and e_2 during mode 1 of the $(n+1)$th half-cycle.

Mode 2 is defined when one core saturates. Core *1* can and will saturate during the *n*th half-cycle except for quiescent conditions. When core *1* saturates, the load current i_L will increase and no longer be negligible. Fig. 5 is the equivalent circuit of Fig. 4 for mode 2 of the *n*th half-cycle. The voltage equations of Fig. 5 are

$$e_s=i_L(R_K+R_L)-i_CR_K+e_2-e_2 \tag{7}$$

$$e_c=i_LR_K-i_C(R_K+R_C)-e_2\frac{N_C}{N_L} \tag{8}$$

The ampere-turn relationship for core *2* is

$$(NI_0)=i_L(N_L-N_F)+i_CN_C=i_CN_C \tag{9}$$

Again the coercive force (NI_0) is considered zero and equations 7, 8, and 9 are solved for e_2 and i_L.

$$e_2=e_s\frac{N_L}{N_C}\frac{R_K}{R_K+R_C}-e_C\frac{N_L}{N_C} \tag{10}$$

$$i_L=\frac{e_s}{R_K+R_L} \tag{11}$$

Equation 10 is the expression for the voltage across the N_L winding of core *2* during mode 2 of the *n*th half-cycle. The voltage across core *1* is zero because core *1* is saturated. Equation 11 is the expression for the load current during mode 2 and will hold true for both the *n*th and the $(n+1)$th half-cycles because of the symmetry of the circuit.

The only thing remaining before the voltage e_2 can be completely described for the *n*th and the $(n+1)$th half-cycles is a factor relating the duration of modes 1 and 2. Let the factor $a(n)$ be the ratio of the volt-time area of the supply voltage e_s during the saturation of core *1* to the total volt-time area of the supply voltage. As $a(n)$ is defined for the *n*th half-cycle, $a(n+1)$ is defined similarly for the $(n+1)$th half-cycle. From equations 6, 10, and the factor $a(n)$, the average voltage across the N_L winding of core *2* for the complete *n*th half-cycle is

$$E_2(n)=[1-a(n)]\left[\frac{E_s}{2}-\frac{N_L}{N_C}E_C(n)\right]+ a(n)\frac{N_L}{N_C}\left[E_S\frac{R_K}{R_K+R_L}-E_C(n)\right] \quad (12)$$

Similarly, using equation 5 and the factor $a(n+1)$, E_2 for the $(n+1)$th half-cycle is

$$E_2(n+1)=[1-a(n+1)]\frac{E_s}{2} \quad (13)$$

During a complete cycle of operation of any reactor that begins and ends with the same amount of flux, there is no change in the net amount of flux. If there is no change in the net amount of flux, the net average voltage across the reactor during the complete cycle is zero.

By studying the operation of core *2* for the *n*th and the $(n+1)$th half-cycles, it can be seen that the flux at the beginning of the *n*th is the same as the flux at the end of the $(n+1)$th. Thus the average voltage of core *2* over a complete cycle is zero or

$$E_2(n)=E_2(n+1) \quad (14)$$

The equations for the average output voltage across R_L for the two half-cycles are

$$E_0(n)=a(n)I_L(n)R_L=a(n)\frac{E_S}{R_L+R_K}R_L \quad (15)$$

$$E_0(n+1)=a(n+1)I_L(n+1)R_L= a(n+1)\frac{E_S}{R_L+R_K}R_L \quad (16)$$

Solving equations 15 and 16 for $a(n)$ and $a(n+1)$ yields

$$a(n)=\frac{E_0(n)}{E_S}\frac{R_K+R_L}{R_L} \quad (17)$$

$$a(n+1)=\frac{E_0(n+1)}{E_S}\frac{R_K+R_L}{R_L} \quad (18)$$

Equations 12, 13, 14, 17, and 18 are combined and solved for $E_0(n+1)$. In simplifying these equations it has been assumed that E_c is much less than E_s and that N_L is not more than an order of magnitude greater than N_C.

$$E_0(n+1)=\frac{2N_L}{N_C}\frac{R_L}{R_L+R_K}E_C(n)+ \left(1-\frac{2N_L}{N_C}\frac{R_K}{R_K+R_L}\right)E_0(n) \quad (19)$$

Equation 19 describes the average output voltage on one half-cycle as a function of the average control voltage and the average output voltage on the previous half-cycle.

Appendix II

Fig. 6 is the diagram of the amplifier to be analyzed. This analysis will differ from that of Appendix I only in that the "boosting" circuit has been added. From Fig. 6, mode 1 of the *n*th half-cycle, the ampere-turn relationships for the cores are

$$\text{Core } 1\ (NI_0)=i_LN_L+i_PN_P-i_CN_C- i_HN_H \quad (20)$$

$$\text{Core } 2\ (NI_0)=i_LN_L-i_PN_P+i_CN_C+ i_HN_H \quad (21)$$

When $N=N_L=N_P$ and $N_C=N_H$, equations 20 and 21 combine to yield

$$I_0=i_L=i_P \quad (22)$$

$$\frac{N_L}{N_C}I_0=i_C+i_H \quad (23)$$

The coercive force (NI_0) is not assumed zero until the voltage drop produced by the magnetizing current through R_H can be compared with the rest of the circuit voltages. That is, R_H is not restricted to a relatively low value as are R_K, R_L, R_C, and R_P and thus may have an appreciable voltage drop even though I_0 is small. The voltage equations for mode 1 of the *n*th half-cycle from Fig. 7 are

$$e_S=e_1+e_1+e_2-e_3+i_L(R_K+R_L+R_P)- i_CR_K-i_HR_P \quad (24)$$

$$\frac{N_C}{N_L}e_1=i_C(R_C+R_K)-i_LR_K+e_C+\frac{N_C}{N_L}e_3 \quad (25)$$

$$\frac{N_C}{N_L}e_1=i_H(R_H+R_P)+i_LR_P+\frac{N_C}{N_L}e_3 \quad (26)$$

Equations 22 through 26 are solved for e_1 and e_3 with the assumptions that e_c is at least slightly greater than zero and that R_H is much larger than $(R_P+R_K+R_C+R_L)$

$$e_1=\frac{e_S}{2} \quad (27)$$

$$e_2=\frac{e_S}{2}-\frac{N_L}{N_C}e_C \quad (28)$$

Equation 28 is the voltage across the N_L winding of core *2* during mode 1 of the *n*th half-cycle. Because of the switching action of the rectifiers, equation 27 is the voltage across the N_L winding of core *2* during mode 1 of the $(n+1)$th half-cycle.

If core *1* saturates during the *n*th half-cycle, the load current will increase. Fig. 8 is the equivalent circuit for mode 2 of the *n*th half-cycle. The voltage equations for Fig. 8 are

$$e_s=i_L(R_K+R_P+R_L)-i_CR_K-i_HR_P+ e_2-e_3 \quad (29)$$

$$i_LR_K=i_C(R_C+R_K)+e_C+\frac{N_C}{N_L}e_3 \quad (30)$$

$$i_LR_P=i_H(R_H+R_P)-\frac{N_H}{N_L}e_3 \quad (31)$$

The ampere-turn relationship for core *2* is

$$(NI_0)=i_CN_C-i_HN_H \quad (32)$$

Equations 29 through 32 are solved for i_L and e_2 yielding

$$i_L=\frac{e_S}{R_K+R_P+R_L} \quad (33)$$

$$e_2=\frac{N_S}{N_C}\left[\frac{R_K}{R_K+R_P+R_L}e_S-e_C\right] \quad (34)$$

By use of equations 27, 28, and 34, the expressions for the average voltages across core *2* for the two half-cycles are

$$E_2(n)=[1-a(n)]\left[\frac{E_S}{2}-\frac{N_L}{N_C}E_C(n)\right]+ a(n)\frac{N_L}{N_C}\left[E_S\frac{R_K}{R_K+R_L+R_P}-E_C(n)\right] \quad (35)$$

$$E_2(n+1)=[1-a(n+1)]\frac{E_S}{2} \quad (36)$$

Following the argument of Appendix I,

$$E_2(n)=E_2(n+1) \quad (37)$$

The factors $a(n)$ and $a(n+1)$ equal

$$a(n)=E_0(n)/I_L(n)R_L= \frac{E_0(n)}{E_S}\frac{R_K+R_P+R_L}{R_L} \quad (38)$$

$$a(n+1)=E_0(n+1)/I_L(n+1)R_L =\frac{E_0(n+1)}{E_S}\frac{R_K+R_P+R_L}{R_L} \quad (39)$$

The last five equations are combined in a similar manner used in Appendix I and solved for

$$E_0(n+1)=\frac{2N_L}{N_C}\frac{R_L}{R_K+R_L+R_P}E_C(n)+ \left[1-\frac{2N_L}{N_C}\frac{R_K}{R_K+R_L+R_P}\right]E_0(n) \quad (40)$$

Equation 40 describes the average output voltage on one half-cycle as a function of the average control voltage and the average output voltage on the previous half-cycle.

Appendix III

Analysis for constant current in the control circuit with changing control voltage E_C is carried out with reference to the circuit of Fig. 7. It is assumed that the windings $N_c=N_H$ in addition to the preliminary assumptions made in the other analyses. When $N_C=N_H$, the voltages across N_{C1} and N_{H1} are equal and the voltages across N_{C2} and N_{H2} are equal. Thus, in Fig. 7 the equal sets have been noted as e_1 and e_3 respectively. The voltage equations for the control and the "boosting" circuits are

$$e_1=i_C(R_C+R_K)+E_C+e_3-i_LR_K \quad (41)$$

$$e_1=i_H(R_H+R_P)+i_LR_P+e_3 \quad (42)$$

Subtracting equation 41 from equation 42 yields

$$i_H(R_H+R_P)+i_LR_P=i_C(R_C+R_K)+ E_C-i_LR_K \quad (43)$$

For the polarity of e_s, noted in Fig. 7, core *2* remains unsaturated for the entire half-cycle. The equation for the ampere-turn relationship of core *2* is

$$(NI_0)=i_L(N_L-N_F)+i_CN_C+i_HN_H \qquad (44)$$

Letting $N=N_L$ and substituting equation 44 into 43 and solving for i_C yields

$$i_C=\left[\frac{N_L}{N_C}\frac{R_H+R_P}{R_H+R_P+R_C+R_K}\right]I_0+ \left[\frac{R_P+R_K}{R_H+R_P+R_C+R_K}\right]i_L- \left[\frac{1}{R_H+R_P+R_C+R_K}\right]E_C \qquad (45)$$

It is desired that i_c remain constant with E_C. That is, the control current is to remain a constant value of direct current for a range of control voltage. When and if this condition can be accomplished, it would be relatively easy to add another winding supplied by a constant current source to each core and reduce the control current to zero.

To find the conditions necessary for a constant i_c with respect to E_c, differentiate i_c in equation 45 with respect to E_C and set the differential equal to zero. This yields

$$1=\frac{N_L}{N_C}(R_H+R_P)\frac{dI_0}{de_c}+(R_P+R_K)\frac{di_L}{de_c} \qquad (46)$$

where $\frac{dI_0}{de_c}$ is the change in magnetizing current with respect to the control voltage caused by the sloping of the hysteresis loop and $\frac{di_L}{de_c}$ is the change in load current for a change in control voltage. For one-half-cycle response $\frac{di_L}{de_c}=\frac{dE_0/de_c}{R_L}=\frac{1}{R_K}$ from equation 40 in Appendix II. Under these conditions equation 46 becomes

$$-\frac{dI_0}{de_c}=\frac{N_C}{N_L}\frac{R_P}{R_H+R_P}\frac{1}{R_K} \qquad (47)$$

Equation 47 shows the adjustment of R_P and R_H necessary to compensate for a negative slope of the hysteresis loop. When equation 47 is satisfied, the amplifier of Fig. 7 will have a constant control current for changing control voltages and a response time of one half-cycle of the power supply frequency.

Representation of Nonlinear Characteristics by Linear Elements

M. S. M. ABOU-HUSSEIN
ASSOCIATE MEMBER AIEE

THE solution of the modern complicated electrical engineering problems needs simpler methods than dealing with a large number of equations in a large number of unknowns; simpler experimental solutions are introduced in the form of simple equivalent circuits or a collection of such circuits with variable constants (to represent more than one case) and measuring instruments in a suitably designed machine called analogue computer. Hence the importance of facilitating the solution of nonlinear characteristics of magnetic circuits, neglecting hysteresis, by the steady-state response of linear elements and using the ordinary measuring instruments (ammeter and voltmeter) is clear.

In this paper it is explained how the magnetization curve of a d-c loaded magnetic circuit may be represented by the steady-state response of linear elements. The operation of the circuit is simple; one input and one output voltage are related together with the nonlinear equation. Only the output voltage is measured, for a known input voltage after a current meter reading is adjusted, with the use of two identical mechanically coupled variable resistances, to a fixed constant value.

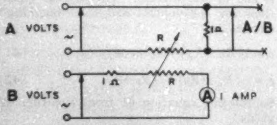

Fig. 1. Obtainment of A/B without measuring A or B

Theory

Before dealing directly with the problem of representation, the following method is given explaining how linear elements may be used to get the value A/B if both A and B are given as isolated voltages though not of known magnitudes and are obtained from the same source (having the same frequency) but through isolating voltage transformers giving output in-phase voltages of magnitudes A and B. Considering Fig. 1 and adjusting the two identical mechanically coupled resistances to the value R corresponding to the flow of 1 ampere in the ammeter

$$B=R+1$$

or

$$R=B-1 \qquad (1)$$

In the form of current, the current in the upper circuit under these conditions will be

$$A/(R+1)=A/B \qquad (2)$$

In the form of voltage, the voltage drop across the 1-ohm resistance of the upper circuit will also be A/B.

In the following representations, using some typical equations of magnetization, transformers are used as voltage multipliers; for a high degree of accuracy of operation of the equation analogue these transformers are to have negligible exciting current and regulation.

FRÖHLICH'S EQUATION ANALOGUE CIRCUITS

Case 1

$y=ax/(b+x)$; x is known, find y (3)

The analogue circuit is shown in Fig. 2 There are two isolated voltage sources of magnitudes x and b and a transformer of ratio a, so that voltages of magnitudes ax and $(b+x)$ are obtainable and divided as indicated in Fig. 1.; this division is equal to y.

Case 2

Fröhlich's equation may be reduced to the form

Paper 56-121, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted March 22, 1954; made available for printing November 21, 1955.

M. S. M. Abou-Hussein is with the University of Cairo, Giza, Egypt.

Vol.
Pt. 1
1956

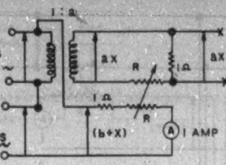

Fig. 2 (left). Solution of Fröhlich's equation: x is known, find y; $y=ax/(b+x)$

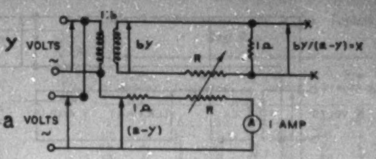
Fig. 3 (right). Solution of Fröhlich's equation: y is known, find x; $x=by/(a-y)$



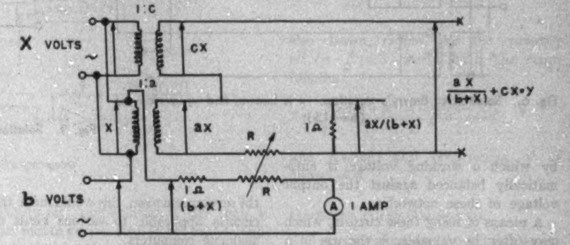


Fig. 4. Solution of modified Fröhlich's equation: x is known, find y; $y=[ax/(b+x)]+cx$

$$x=yb/(a-y);\ y \text{ is known, find } x \qquad (4)$$

which is the same equation as for case 1 but with x, y, a, and b replacing y, x, b, and a respectively and with a subtraction sign instead of an addition sign for case 1; Fig. 3 will be the required analogue circuit for this case.

Modified Fröhlich's Equation Analogue Circuits

Case 1

$$y=[ax/(b+x)]+cx;\ x \text{ is known, find } y \qquad (5)$$

Fig. 4 is the analogue circuit for this case; this figure is the same as Fig. 2 but with a second transformer circuit, so that a voltage of magnitude of cx is obtained and added to the voltage $ax/(b+x)$ across the 1-ohm resistance of the medium circuit; the sum being y.

Case 2

The modified Fröhlich's equation may be transferred to the form

$$y'=y-cx=ax/(b+x)$$

or

$$x=y'b/(a-y');\ y \text{ is known, find } x \qquad (6)$$

which is the same equation as case 2 of Fröhlich's equation so that Fig. 3 may be used but with y' replacing y and with an additional circuit giving the value of cx which is added to y'; the sum being y which is parallelled to the final input voltage, as shown in Fig. 5.

Emery's Equation Analogue Circuits

Using the same principles of voltage addition, subtraction, and division, Emery's equation of saturation of magnetic circuits could be represented in a similar way, as shown in Fig. 6, for the equation

$$y=k-[k/(mx+Lk)],\ x \text{ is known, find } y \qquad (7)$$

In Fig. 7 Emery's equation is shown for case 2 where the equation is transferred to the form

$$x=(k/m)[(k-y)^{-1}-L] \qquad (8)$$

Notes:

1. For cases 1, if x is known and changed to another value, the effect of saturation according to the set-up equation will be considered by varying the resistance R until the ammeter reads 1 ampere; then the indicated value of y will be the new value.

2. For cases 2, note 1 is repeated, replacing x by y and y by x.

3. The directions of x, y, and the applied voltages could be fixed by assuming one constant direction for positive values and the reverse direction for negative ones.

4. Direct current may be used in the analogue circuits instead of the alternating current by choosing appropriate values of potential dividers replacing transformers, the ratios of which are rendered to unity or less by representing the equation constants and variable quantities to scale in the analogue circuits.

5. It is important to notice that only d-c loaded magnetic circuits are considered in the previous representations.

6. The frequency value that may limit the operation of the circuits is either the value which makes the transformer series impedance comparable to $(R+1)$ or that value which causes resonance between the circuit inductances and stray capacitances at high frequencies.

Conclusions

It is thus possible to represent nonlinear equations of the form given by simple linear electric analogues. The accuracy of operation of the circuits is dependent on the degree of perfectness of the elements used, the method of their loading, the degree of supression of the effects of the transformer magnetizing circuits, and the supply harmonics and nonconstancy. Test results might have been given but the accuracy will vary from one type of equipment to another, and results given for one type of equipment will not apply to another. Furthermore, this type of inaccuracy is well known.

Using compensated transformers throughout the analogues, and with the existing tendency toward the use of automatic devices, it would be possible to arrange accurately automatic means to maintain the adjustments required in the circuits and to provide a balancing means

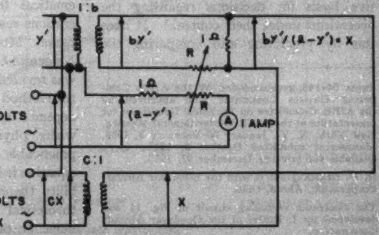

Fig. 5. Solution of modified Fröhlich's equation: y is known, find x; $y'=y-cx=ax/(b+x)$.

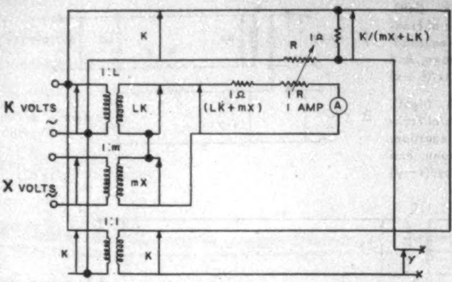

Fig. 6. Solution of Emery's equation: x is known, find y, $y = k - [k/(mx+Lk)]$

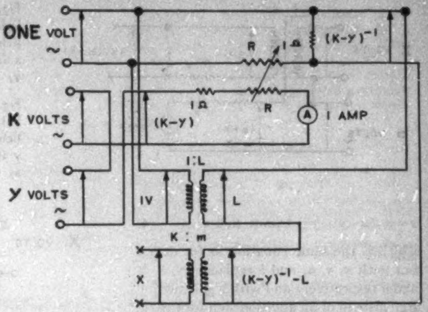

Fig. 7. Solution of Emery's equation: y is known, find x, $x = (k/m)[1/(k-y)-L]$

by which a working voltage is automatically balanced against the output voltage of these networks.

A means of using these circuits, which may often be valuable, is the use of a servomechanism system to position the potentiometer automatically. Within the limits of the speed of response on the servomechanism, this would make the circuits applicable to various kinds of analogue computers.

Hence the d-c loaded magnetic cores, which are often included in the many machines, instruments, apparatus, etc., would be thus accurately represented in a simple way with the use of linear elements, taking saturation into account, by feeding the given circuits into different analogue computers which include such electromagnetic equipment.

Analogue Computer Generation of Probability Distributions for Operations Research

N. D. DIAMANTIDES
ASSOCIATE MEMBER AIEE

OPERATIONS research is being applied in science, commerce, and industry. Developed in response to military needs during World War II, it was then known as operations analysis and later as weapons systems evaluation. In its most general aspect operations research is a scientific method of providing executive departments with a quantitative basis for decisions regarding the operations under their control.[1] It does this by predicting and comparing the values, effectiveness, and costs of alternative courses of action involving man-machine systems.

Monte Carlo Method

The most important single mathematical tool of operations research is probability and statistical theory.[1] One mathematical technique used in many operations research problems was given the name "Monte Carlo Method" by von Neumann,[2] during World War II when it was revived at Los Alamos. In general, the method is used to solve problems that depend upon probability interference where physical experimentation is impracticable and the creation of an exact equation is impossible. While the probability theory derives its equations from theoretical factors based on the phenomenon of chance, in the Monte Carlo method an answer is sought with the use of probability to a physical question often having no relation to probability except as a tool. The technique is based on the construction of a mathematical model. The model describes the behavior of related numbers assumed to bear a correspondence to events associated with physical reality. The numbers are selected at random in accordance with the statistical character of the input quantities to the model, but the operations imposed on them follow the rules of the model. Thus, the behavior of the output variable of the particular problem can be obtained by means of calculations prescribed by the model.

Probability Distribution Generation

RANDOM-NOISE GENERATOR

Application of analogue computers to operations research problems by use of the Monte Carlo method requires a source of the probability distributions most frequently encountered in applied science. One source is an electronic random-noise generator utilizing the noise component of a thyratron plate voltage kept in a condition of constant discharge. The output component is subjected to a 2-stage amplification, Fig. 1, after which the pulse peaks trigger a blocking oscillator. The output of the oscillator is a

14	15	20	138	26	33		

series of identical pulses with the pulse rate obeying a Gaussian distribution. By means of a monostable multivibrator following the oscillator stage, the grid bias of the first amplification stage is adjusted automatically to ensure a constant mean counting rate. The output of the oscillator, acting through a flip-flop and a buffer amplifier, switches in opposite directions the two parallel feedback impedances of another d-c amplifier *A*. When the electronic switch 1 is "on," switch 2 is "off," point *C* is at zero potential, and the only input to output amplifier *B* is the reference voltage $+e$. When switch 1 is off and switch 2 is on, point *C* is at $-2e$ potential and the effective input to amplifier *B* is $-e$. A symmetric square-wave output, e_0, results with the duration of the alternate pulses being governed by the Gaussian distribution of the oscillator output. The noise generator can be combined with analogue computer operational units to generate not only Gaussian but other random distributions.

Gaussian Amplitude Distribution

The number n of the blocking oscillator output pulses per 0.33 second was measured for a typical test run. The results, as shown in Table I, were used to check the adequacy of fit of the pulse-rate frequency. An indication of whether the Gaussian distribution applies can be obtained by making use of the so-called probability chart. The abscissa scale of this chart is nonuniform, following the law of normal probability. If the plot of n versus percentage of cases is a straight line, it can be assumed that the phenomenon does obey the normal law. Engineering phenomena cannot be counted on to follow the normal law closely into probabilities of less than 1 per cent or greater than 99 per cent.[3] The pulse rate in this case shows a satisfactory degree of Gaussian distribution; see Fig. 2. The mean counting rate is $N=20$ pulses per 0.33 second and the standard deviation is $\sigma=3.2$ pulses per 0.33 second. Thus, the probability distribution will be

$$P(n)=\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{(n-N)^2}{2\sigma^2}} \tag{1}$$

$$P=0.124e^{-\frac{(n-20)^2}{20.48}} \tag{2}$$

N is determined by the ordinate corresponding to the value 50 of the percentage of cases; σ is given by the difference of N and the ordinate at 84.13 per cent. In the same plot, the standard-error band is also drawn, defined by the quantity erf $(n-N)\pm S$, where erf is the error-function

$$S=\sqrt{\frac{[\operatorname{erf}(n-N)][1-\operatorname{erf}(n-N)]}{Z}}$$

and Z = the total occurrences of all values of n.

Gaussian Pulse Generator

One convenient way for obtaining a sequence of random numbers of Gaussian magnitude distribution for use in place of the standard tables required by digital computers is by generating a train of identical pulses of rate n and summing them over a selected constant interval. As shown in Fig. 3, a properly limited differentiator and a rectifier, both in series with the noise generator, will provide a pulse at each zero-crossing of the square-wave output. Summing these pulses over the unit time interval will result in a total numerically equal to the pulse rate. At the end of such intervals the output of the summer will attain values which, like the pulse rate itself, will be Gaussian.

GAUSSIAN PULSE-RATE GENERATOR

Fig. 4. Random-distribution generator

A continuous output can be obtained by filtering the noise-generator output through a sharp cutoff low-pass filter; this will not alter the Gaussian nature of the signal.[4] However, the cutoff frequency should be of a value at which the power has not dropped off appreciably. The integrator output will then exhibit the Gaussian amplitude distribution

$$P(V)=\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{(V-V_0)^2}{2\sigma^2}} \tag{3}$$

Other Amplitude Distributions

The most important feature of the Gaussian pulse generator is its ability to create other random distributions. Assume that a second randomly varying voltage $v=f(V)$, is sought, the instantaneous values of which will show a one-to-one correspondence to the random values of V. The probability $Q(v)$ that the voltage v lies in the interval $(v, v+dv)$ must equal the probability $P(V)$ that voltage V lies in the interval $(V, V+dV)$. Consequently,[5] $Q(v)dv=P(V)dV$

$$\text{or } v=\int_a^V \frac{P}{Q}dV \tag{4}$$

where a is an arbitrary constant that can be taken as $a=0$. Then, according to equation 3

$$v=\frac{1}{\sigma\sqrt{2\pi}}\int_a^V \frac{e^{-\frac{(V-V_0)^2}{2\sigma^2}}}{Q}dV \tag{5}$$

Equation 5 establishes the basic operation for the generation of a variety of random distributions as shown by the examples in the Appendix. Besides the ones listed there, the linear, hyperbolic, inverse quadratic, and inverse Gaussian distributions were also evaluated.

Circuitry for Probability Transformation

To obtain any of the distributions described in the Appendix, it will be necessary to implement the pertinent equation on the computer. This will require one function generator following the Gaussian source of V. For every value V, then,

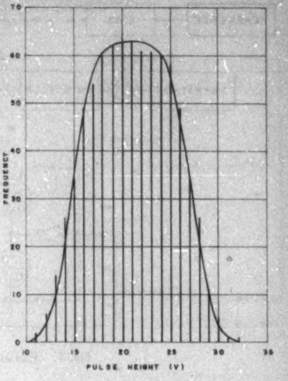

Fig. 5. Gaussian number distribution, measured

the corresponding voltage v will be generated, with its amplitude obeying the selected distribution $Q(v)$. As an example, the generation of a "flat" or uniform distribution was tried as required by equation 12. Fig. 4 shows the details of the computer circuit. The upper part of the diagram is a timer operating a sampling switch S. With the setting shown, the switch stays open for 1 second and closes for about 0.05 second to discharge the random-number integrator. At the lower part of the diagram the generator square wave is differentiated, limited to ensure constant pulse height, and rectified. The resulting pulse trains are summed by the random-number integrator. Fig. 5 shows both the experimental and theoretical data for a mean counting rate of nine counts per clock pulse. The number magnitude V is given in volts and the mean V_0 and the standard deviation σ were calculated as $V_0=21$ volts, and $\sigma=5.2$ volts, by means of a probability plot similar to that of Fig. 2. Consequently

$$P(V)=0.077e^{-\frac{(V-21)^2}{54.08}} \tag{6}$$

Generally, the distribution will be of the form given by equation 1. Since the uniform distribution is sought, application of equation 13 gives

$$v=\frac{1}{k\sigma\sqrt{2\pi}}\int_0^V e^{-\frac{(V-V_0)^2}{2\sigma^2}}dV \tag{7}$$

With

$$\frac{V-V_0}{\sigma}=x \tag{8}$$

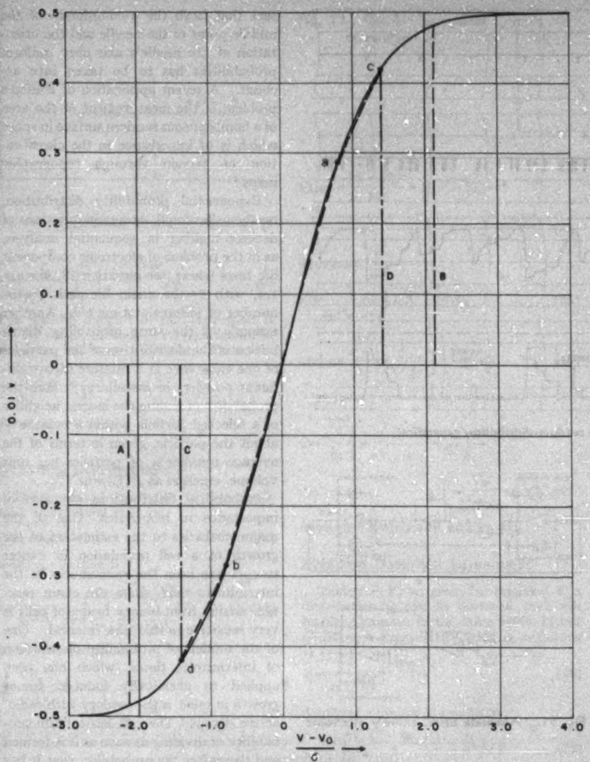

Fig. 6. Function generator characteristics

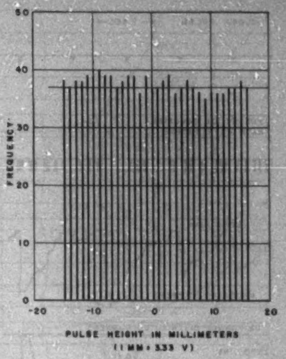

Fig. 8. Uniform number distribution, measured

equation 7 becomes

$$v=\frac{1}{k\sqrt{2\pi}}\int_{-\frac{V_0}{\sigma}}^{\frac{V-V_0}{\sigma}}e^{-\frac{x^2}{2}}dx \qquad (9)$$

$$\text{or } v=\frac{1}{k\sqrt{2\pi}}\int_{-\infty}^{\frac{V-V_0}{\sigma}}e^{-\frac{x^2}{2}}dx-$$

$$\frac{1}{k\sqrt{2\pi}}\int_{-\infty}^{-\frac{V_0}{\sigma}}e^{-\frac{x^2}{2}}dx \qquad (10)$$

This yields[1]

$$v=\frac{1}{k}\left[\operatorname{erf}\left(\frac{V-V_0}{\sigma}\right)-\operatorname{erf}\left(-\frac{V_0}{\sigma}\right)\right] \qquad (11)$$

On the basis of a table for erf(x) and of the values of V_0 and σ already derived, the function v is obtained as shown in Fig. 6. The abscissas have been normalized according to equation 8, and k is taken equal to 0.01.

The measured values of V fall within the ordinates A and B of Fig. 6. It is obvious that if the range is limited to the values of V between the lines C and D, i.e., $28.8>V>13.2$, then the v function can be approximated by the three straight-line segments *ca-ab-bd* without appreciable loss of accuracy.

The simulation circuit for the generation of the function *c-a-b-d* is shown in Fig. 7, along with the required settings. The computations were based on the assumption that one σ is represented by 5.2 volts in the function generator input. Fig. 8 gives the results of one run (1,126 numbers); Fig. 9 is a small portion of the run. A second application of the method was tried, the aim being the generation of the inverse Gaussian distribution. The results are shown in Fig. 10.

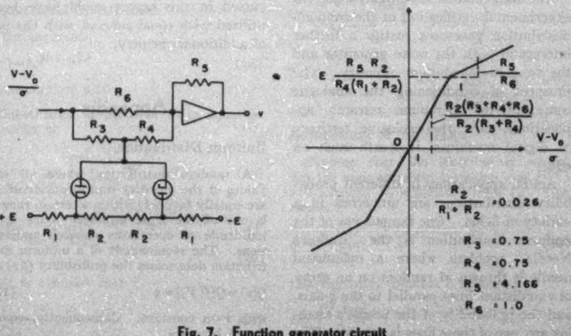

Fig. 7. Function generator circuit

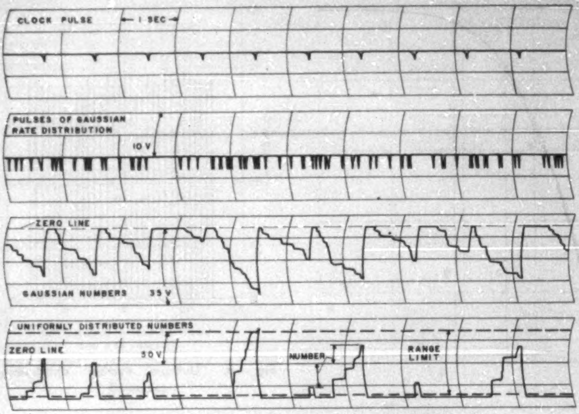

Fig. 9. Portion of run for uniform random-distribution generation

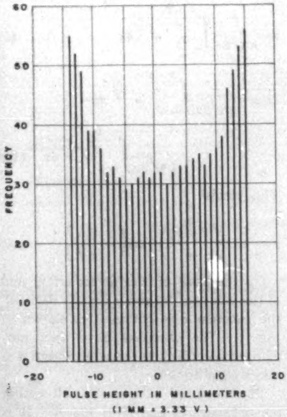

Fig. 10. Inverse Gaussian number distribution, measured

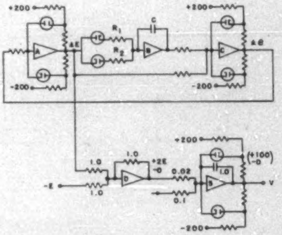

Fig. 11. Alternate timer, entirely electronic

Note on Relay in Sampling Circuit

A relay in the sampling circuit could be objectionable when higher speeds are required. In this case the purely electronic switching circuit shown in Fig. 11 can be utilized. The output of amplifier A is a square wave $\pm E$, with the duration of the halves adjusted by the time constants R_1C and R_2C (amplifier B). The addition of a $-E$ voltage in amplifier D results in equally spaced pulses $+2E$. When these pulses are fed (through an impedance assuring high gain) into the integrator that produces the Gaussian numbers V, they cancel the integrator output and prepare the integrator for the next number.

Discussion

The mathematical investigation and the experimental verification of the random-distribution generator justify a further interest in both the noise generator and the random-distribution circuitry. The prospect of conditioning the analogue computer to operations research applications, now the exclusive territory of digital machines, is worth such an effort.

Actual applications of different probability distributions are numerous in a variety of fields. One famous use of the uniform distribution is the "Buffon's Needle" problem where a cylindrical needle is thrown at random on an array of equidistant lines parallel to the x-axis, and the probability of the needle's crossing any one of these lines is sought. The fact that both the y-co-ordinate of the middle point of the needle and the orientation of the needle's axis obey uniform probabilities has to be taken into account. A recent application of Buffon's problem is the measurement of the area of a homogeneous random surface in space which is of importance in the classification of terrain through topographic maps.[6]

Exponential probability distribution, on the other hand, occurs in questions of decision-making in sequential analysis, as in the problem of electronic component life tests where, see equation 18, $k_6=a=1/\theta$, with θ=the mean life and V=the number of failures at time t.[7,8] Another example of the same probability distribution is the distribution of the particles of one substance in a mixture of two different powders in metallurgy;[9] here the probability of finding the nearest neighbor of a selected particle within a volume V about the particle, given in terms of the average number n of particles per unit volume, emerges as $P(V)=n\epsilon^{-Vn}$.

Probability distributions are also of importance in biophysics. One of the major obstacles to the estimation of the growth of a cell population in cancer tumors has been the randomness of the intermitotic time, since the chain reaction arising from binary fission of cells is very sensitive to this time interval. One of the models of probability distribution of intermitotic times, which has been applied to chemically induced tumor growth in mice, is the analogy with radioactive decay. The cell has a finite probability of dividing as soon as it is formed and thereafter the probability that it has not divided decreases exponentially. At the Los Alamos Scientific Laboratories, studies were conducted lately on this problem using Monte Carlo methods implemented by the MANIAC digital computer.[10] Obviously the technique discussed in this report could have been utilized with equal success, with the use of additional circuitry.

Appendix

Uniform Distribution

A random distribution where all the values of the quantity under consideration are equally favored (within a certain range) is one of the most important ones in a multitude of operations research applications. The requirement of a uniform distribution determines the probability $Q(v)$ as

$$Q(v)=Q[f(V)]=k \tag{12}$$

with k=a constant. Consequently, equation 5 becomes

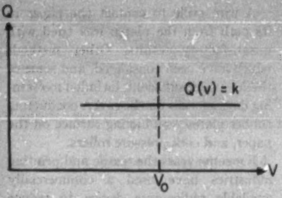

Fig. 12. Erf, definite integral of equation 13

$$v=\frac{1}{k\sigma\sqrt{2\pi}}\int_0^V e^{-\frac{(V-V_0)^2}{2\sigma^2}}\,dV \tag{13}$$

The definite integral of this expression is the erf which, because of its significance in statistics, has been tabulated. Thus

$$v=\frac{1}{k}\left[\operatorname{erf}\left(\frac{V-V_0}{\sigma}\right)-\operatorname{erf}\left(\frac{a-V_0}{\sigma}\right)\right] \tag{14}$$

shown graphically in Fig. 12.

Quadratic Distribution

The analytical expression for the quadratic distribution will be

$$Q(v)=k_2(V-V_0)^2 \tag{15}$$

making equation 5

$$v=\frac{1}{k_2\sigma\sqrt{2\pi}}\int_{V_a}^{V}\frac{e^{-\frac{(V-V_0)^2}{2\sigma^2}}}{(V-V_0)^2}\,dV \tag{16}$$

under the condition

$$\frac{V-V_0}{V_a-V_0}>1$$

$$\text{or } v=\frac{1}{k_2\sigma}\left[\operatorname{erf}\left(\frac{V-V_0}{\sigma}\right)-\operatorname{erf}\left(\frac{V_a-V_0}{\sigma}\right)\right]+$$

$$\frac{1}{k_2\sigma\sqrt{2\pi}}\left[\frac{e^{-\frac{V_a^2}{2\sigma^2}}}{V_a-V_0}-\frac{e^{-\frac{V^2}{2\sigma^2}}}{V-V_0}\right] \tag{17}$$

shown graphically in Fig. 13, which is a type-II Pearson distribution.[11]

Exponential Distribution

The expression

$$Q(v)=k_6e^{a(V-V_0)} \tag{18}$$

where $a>0$ or $a<0$.

Substitution of equation 16 in equation 5 results in

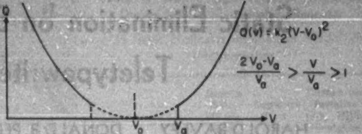
$$v=\frac{1}{k_6\sqrt{2\pi\sigma}}\int_0^V\frac{e^{-\frac{(V-V_0)^2}{2\sigma^2}}}{e^{a(V-V_0)}}\,dV \tag{19}$$

$$\text{or } v=\frac{1}{k_6\sigma\sqrt{2\pi}}\int_0^V e^{-\frac{(V-V_0)^2}{2\sigma^2}-a(V-V_0)}\,dV \tag{20}$$

If it is assumed that

$$\frac{y}{\sqrt{2}\sigma}=\frac{V-V_0}{\sqrt{2}\sigma}+\frac{a\sigma}{\sqrt{2}} \tag{21}$$

Fig. 13. Graphic expression of equation 17



$$\text{then } -\frac{(V-V_0)^2}{2\sigma^2}-a(V-V_0)=$$

$$-\frac{y^2}{2\sigma^2}+\frac{a^2\sigma^2}{2} \tag{22}$$

Therefore

$$v=\frac{1}{k_6\sigma\sqrt{2\pi}}\int e^{\frac{a^2\sigma^2}{2}-\frac{y^2}{2\sigma^2}}\,dy \tag{23}$$

$$\text{and } v=\frac{e^{\frac{a^2\sigma^2}{2}}}{k_6}\,\frac{1}{\sigma\sqrt{2\pi}}\int e^{-\frac{y^2}{2\sigma^2}}\,dy \tag{24}$$

This results in

$$v=\frac{e^{\frac{a^2\sigma^2}{2}}}{k_6}\left[\operatorname{erf}\left(\frac{V-V_0}{\sigma}+a\sigma\right)-\right.$$

$$\left.\operatorname{erf}\left(-\frac{V_0}{\sigma}+a\sigma\right)\right] \tag{25}$$

expressed graphically in Fig. 14.

Standard Deviation Adjustment

Taking $P(V)$ as given by equation 3, a distribution Q can be obtained that will be also Gaussian of the same mean V_0 but of different standard deviation σ_0, as follows

$$Q=\frac{1}{\sigma_0\sqrt{2\pi}}e^{-\frac{(V-V_0)^2}{2\sigma_0^2}} \tag{26}$$

Applying equation 5 results in

$$v=\frac{\sigma_0}{\sigma}\int_0^V e^{\frac{(V-V_0)^2}{2}\left(\frac{1}{\sigma^2}-\frac{1}{\sigma_0^2}\right)}\,dV \tag{27}$$

$$v=\frac{\sigma_0}{\sigma}\int_0^V e^{\frac{-\frac{(V-V_0)^2}{2\sigma^2\sigma_0^2}}{\sigma_0^2-\sigma^2}}\,dV \tag{28}$$

Consequently

$$v=\frac{\sigma_0^2\sqrt{2\pi}}{\sqrt{\sigma_0^2-\sigma^2}}\left[\operatorname{erf}\left(\frac{V-V_0}{\frac{\sigma_0\sigma}{\sqrt{\sigma_0^2-\sigma^2}}}\right)-\right.$$

$$\left.\operatorname{erf}\left(\frac{-V_0}{\frac{\sigma_0\sigma}{\sqrt{\sigma_0^2-\sigma^2}}}\right)\right] \tag{29}$$

Adjustment of the Mean

Suppose that the distribution sought has the same standard deviation σ as $P(V)$ but its mean V_n is different from V_0. This means

$$Q=\frac{1}{\sigma\sqrt{2\pi}}e^{-\frac{(V-V_n)^2}{2\sigma^2}} \tag{30}$$

Consequently, equation 5 becomes

$$v=\int_0^V e^{-\frac{1}{2\sigma^2}[(V-V_0)^2-(V-V_n)^2]}\,dV \tag{31}$$

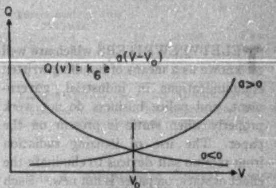


Fig. 14. Graphic expression of equation 25

$$\text{or } v=\int_0^V e^{\frac{V_n^2-V_0^2}{2\sigma^2}-\frac{V_n-V_0}{\sigma^2}V}\,dV \tag{32}$$

$$\text{and } v=e^{\frac{V_n^2-V_0^2}{2\sigma^2}}\int_0^V e^{\left(\frac{V_n-V_0}{\sigma^2}\right)V}\,dV \tag{33}$$

which after the integration becomes

$$v=\frac{\sigma^2}{V_n-V_0}e^{\frac{V_n^2-V_0^2}{2\sigma^2}}\left[1-e^{\left(\frac{V_n-V_0}{\sigma^2}\right)V}\right] \tag{34}$$

Static Elimination on Bell System Teletypewriters

HAROLD BAVLEY
NONMEMBER AIEE

DONALD B. PERRY
MEMBER AIEE

B. S. SWEZEY
NONMEMBER AIEE

TELETYPEWRITERS which are well known as a means of handling written communications in industrial, government, and police business do not work properly when static is present on the paper. The use of ionizing radiation from radium salt devices to eliminate the effect of static on paper is not new. Such a device is now being used on a nationwide basis by the Bell Telephone Companies during the operation of the page and tape teletypewriters. These teletypewriters may be used in many diverse locations on the customer's premises, thus raising the question as to potential health hazards to the customer's attendants, as well as to the telephone company's maintenance forces.

The Problem

In dry winter weather or in some air-conditioned offices where the humidity is relatively low, static electicity is produced on the rolled paper in its path from the teletypewriter platen. The static may cause paper to cling to the back of the teletypewriter cabinet or adjacent wall or it may accumulate inside the teletypewriter cover. The static is caused principally by the action of the type bars in striking the paper and forcing it against the platen, and probably imbedding it momentarily into the platen as each letter is typed.

The production of static charges by the friction of one material against another can be demonstrated by rubbing a glass rod with silk to obtain a positive charge on the rod and a negative charge on the silk. It is not so widely known that static is produced merely by the contact of dissimilar materials with each other, the more nearly perfect the contact, the greater the charge. Compression of an amorphous material (such as rubber) will produce a charge in the material. Collision of one material with another if the relative velocity of motion is over a critical value will also produce a static charge. This charge appears to bear no relation to the amount of energy expended in order to cause the collision. In the case of collision, however, there is a dual effect, one charge due to contact and the other to collision. The two effects may add for some materials or be opposed for others.

Coehn[1–3] determined that the charge Q, which developed as a result of the intimate contact of materials, bore no relation to the length of time the materials were in contact but was proportional to the difference of the dielectric constants of the materials, i.e., $Q=C(K_1-K_2)$ where K_1 and K_2 = the dielectric constants. Richards[4] records his work to determine the value of the constant C and gives an expression $Q=4.43(K_1-K_2)$ where Q is coulombs per centimeter^2 of contact surface in electrostatic units assuming the dielectric constant of steel to be 3.1, and not infinity. The static charge due to contact is appreciable and the effect can be very annoying.

Paper has been known to cling to and climb a wall to the ceiling as it issued from the teletypewriter. Of course, this condition could happen only when the copy is not currently removed from the machine, as might be the case with unattended service or where the machine is automatically started before the office opens and copy is sent to that station from a station in another time zone. Also, copy is sometimes allowed to accumulate on a press wire. To avoid static difficulties, several methods have been tried. One arrangement used was to stretch tinsel with a copper center across the teletypewriter where the paper leaves the platen. The grounded tinsel in contact with the paper removes some of the static charge. However, field reports indicated that trouble still exists and this device was not put into general use.

A wire grille to contact the paper in its path from the platen was tried with unsatisfactory results. Other methods which have been considered, and some of them found insufficient, included moistening devices, rails on the cover, conducting rubber platen, conducting surface on the paper, and cork pressure rollers.

For some years the textile and printing industries have used a commercially available radioactive device to reduce the effect of static charges developed during process operations. This, known as the Ionotron static eliminator, is manufactured by the U. S. Radium Corporation of New York. This device, shown in Figs. 1 and 2, consists of a radium salt distributed throughout thin metal foil bonded to a heavier metallic nonradioactive backing which is then mounted in a suitable housing. The alpha rays and to a lesser extent the beta rays emitted by the radium salt ionize the air in the immediate vicinity so as to make the air conductive. The static is discharged continuously as it is formed. The Ionotron static eliminator for page machines being used for the Bell Telephone Companies' teletypewriters has an active source $7^1/_2$ inches long by 1/4 inch wide, and contains 60 micrograms of radium. These devices are provided with special brackets intended for rapid mounting on the teletypewriters. Each unit has a snap-on nickel steel shield which when removed can be easily attached to the bracket for storage. A silhouette view of location is shown in Fig. 3.

The nature of this radioactive static eliminator requires that precautions be taken in handling since, in addition to the relatively harmless alpha rays, radium emits beta and the more hazardous gamma radiations. The Bell Telephone Companies have issued printed instructions to each maintenance craftsman who may be called upon to install or service the teletypewriters using this means of static elimination. Basically these precautions are as follows:

1. The protective shield should be placed over the active face of the unit and removed only after the eliminator is installed in the teletypewriter.

2. The protective shield should be placed over the active face of the Ionotron when repairs or adjustments are being made to the teletypewriter.

3. When not installed on a teletypewriter, the shielded eliminator should be stored in the original shipping container provided by the manufacturer and then stored in a metal locker away from the immediate area regularly occupied by personnel.

4. In carrying the eliminator to a customer's office for installation, the shielded

unit should be placed in a tool kit and not in a pocket of clothing.

5. The static eliminator should not be dusted or cleaned in the field.

6. Each craftsman is limited to 50 installations a day.

Tests to Determine Degree of Hazard

Tests were made to convince all concerned that if properly used and handled, radiation from the Ionotron static eliminator could be easily controlled.

Health physicists from Tracerlab, Inc., Boston, Mass., and engineers from the Massachusetts Division of Occupational Hygiene co-operated with the Bell System engineers in conducting these tests in which both an ionization chamber instrument and a Geiger tube survey meter were used. Working conditions involving installation and maintenance by company craftsmen in the operation of the teletypewriter, including the changing of the ribbon and paper by the customer's attendant, were simulated, using a model *28* teletypewriter.

Exposure to Maintenance Men

It was estimated that the installation craftsmen's hands would not be at any time in contact with the Ionotron static eliminator for a period greater than two minutes with the protective shield or guard on the unit or for a period of 15 seconds with the protective shield removed. This was borne out by a time study involving two individuals who performed the operation for the first time and who were not accustomed to the machine or the tools. Both of these individuals installed the unit in the teletypewriter and went through the two operations in less than 2 minutes, and in 15 seconds, respectively.

The measurements of the radiation and the estimated dosage per installation are given in Table I.

The figure of 300 milliroentgens (mr), reference 3, refers to whole body radiation.

For partial body radiation to the hands and forearms, the maximum permissible weekly dose is 1,500 milliroentgens (mr).[4]

Reference to Table I indicates that the maintenance craftsmen receive about 0.73 mr per each installation of a static eliminator in the model *28* teletypewriter. Based on the maximum allowable daily dosage, the actual dosage received by the maintenance craftsmen is almost negligible. An additional safety factor is introduced when it is realized that the maximum permissible dosage refers to total body radiation, whereas the exposure would be mainly to the craftsmen's hands during the installation of the unit. However, based on the maximum permissible total body dosage of 60 mr per day, based on a 5-day week, each installation craftsman could install 82 of the *T-35* Ionotron static eliminators without being subjected to an excessive quantity of radiation.

Maintenance

Approximately once a month it may be necessary for a maintenance man to service the teletypewriter for about 1 hour. Table II estimates the dosage of radiation which would be received by a craftsman

Table III. Milliroentgen Dosages Received by Teletypewriter Operators

	Dosage Rate, Mr per Hour	Exposure Time, Hours	Dosage per 8-Hour Day, Milliroentgens
Routine operations			
At keyboard	0.60		
Pelvic region	0.13		
Head region	0.18		
Chest region	0.23		
Knee region	0.13		
Total body maximum possible dosage	0.60	8	4.8
Special operations:			
Changing paper roll	1	0.08	0.08
changing ribbon, 5 minutes per week	1	0.017	0.02
Maximum possible dosage			4.9
Maximum permissible daily dosage			60

Table IV. General Surveys

	Dosage Rate, Mr per Hour	Total Mr per 8-Hour Day	Maximum Permissible Dosage, Per Cent
Adjacent to right side of teletypewriter	0.3	2.4	4.0
Adjacent to left side of teletypewriter	0.4	3.2	5.3
Adjacent to back of teletypewriter	0.4	3.2	5.3
Top at glass surface	15	120	200
Knee hole	0.1	0.8	1.3
Keyboard	0.6	4.8	8.0

based upon 1 hour of service time. Again this is quite small, and it is apparent that a maintenance craftsman could actually be servicing the teletypewriters as a continuous operation based on an 8-hour day, and receive about 16 mr during the entire day. The hands and forearms only are exposed to this radiation. Comparing this dosage with the maximum permissible dosage of 60 mr a day, total body radiation, it is apparent that any maintenance craftsman who follows the specified safety precautions and who would service only a few teletypewriters a day would receive a minimum amount of radiation.

Exposure to Customer's Attendant

During the operation of the teletypewriter, the attendant is seated facing the instrument so that the pelvic region, head region, and chest region are approximately 16 inches, 20 inches, and 16 inches respectively from the static eliminator. The Ionotron static eliminator is located within the machine and is further shielded by the teletypewriter parts, and the metal over the machine. During the sending operation, the attendant's hands are on the keyboard so that only the hands would be directly exposed.

The teletypewriter ribbon is changed about once a week; this requires the opening of the top cover and the insertion of the attendant's hands within the machine for approximately 5 minutes. Similarly, changing the rolls of paper would require less than 5 minutes' exposure per day. Table III gives the total body radiation which may be received for an 8-hour day by a teletypewriter attendant. This results in about only 8 per cent of the maximum permissible total body radiation. Since most of this radiation is received by the hands, this dosage can be considered safe with a large factor of safety.

Other Working Areas

The results of a radiation survey in the immediate vicinity of the no. *28* teletypewriter containing a static eliminator is shown in Table IV, which shows that the radiation levels are low except at the top glass surface. Contact with the glass surface for longer than 4 hours a day every day in the week would lead to obtaining a dosage of 300 mr for that part of the body in contact with glass. It is very unlikely that the top glass surface would be contacted either by the teletypewriter attendant or by others for this period. Other individuals working immediately adjacent to this teletypewriter would be subjected to only a small fraction of the maximum permissible dosage. If these individuals are located more than a foot from the teletypewriter, the radiation exposure to them would be negligible.

In summary, it is the consensus of those participating in the tests that the hazard of radiation is well controlled. The overall exposure to the attendant is considered minimal during the operation of the teletypewriter and during the changing of the paper roll and ribbon. The exposure per machine to the maintenance craftsman, provided the shield is kept on the active face during the installation of the Ionotron static eliminator and during the repair and adjustment of the teletypewriter, would not be excessive. A schedule has been set up to indicate the number of units that each maintenance craftsman will be permitted to install. The radiation received is dependent on the number of teletypewriters which can be serviced in a normal day (of 8 hours) and the amount of radiation received per servicing. Theoretically, the exposure to radiation (unit-shielded) would permit maintenance of about 140 Ionotron-equipped teletypewriters per week. Based on actual experience, the maintenance craftsman could not maintain more than 25 of these teletypewriters per week. Based on actual working conditions, provided the necessary precautions are taken, the maintenance craftsman and the teletypewriter attendant have little to fear from the use of the Ionotron static eliminator.

Measuring 1,800,000-Kw Demand

J. A. MORRIS
NONMEMBER AIEE

H. C. THOMAS
MEMBER AIEE

A PAPER presented by Sporn and Marquis[1] in 1954 outlines quite specifiically practically all phases of the economic, engineering, and financing problems in connection with the supply of 1,800,000 kw of power to the Atomic Energy Commission Portsmouth Area. The measurement of the electrical quantities of this load, to satisfy the contractual requirements, created a number of additional problems, not usually encountered in the measurement of power and energy.

The Problem

The problem involved in the measurement of power and energy of a load of approximately 1,800 megawatts, lies not so much in the magnitude of the load, but rather in the accounting complexities present when this load is supplied by numerous contributors over a complex system of 132- and 330-kv transmission networks. The problem is further complicated by the fact that these networks carry not only power to the 1,800-megawatt load, but also function as carriers of transfer power to and from the interconnected contributors.

Since a number of the tie-line stations are unattended, some means was necessary whereby all power and energy measurements, for two directions of power flow could be recorded simultaneously for each clock hour. It is obvious that accurate readings could be obtained only by some automatic means which would provide a simultaneously printed record for accounting purposes.

In evaluating the numerous devices available for measuring and recording power and energy, the following factors had to be considered.

1. The contractual requirement of an over-all measurement accuracy of ±1%.
2. Initial low loads at supervoltages which would gradually increase to contract value.
3. Combinations of transmission facilities which under certain conditions could change meter loadings by about 300%.
4. The high degree of reliability required for this application, which imposes the need for simple and rapid replacement of defective components, and for equipment designed for operation with a minimum of periodic maintenance.
5. Testing and calibration with usual test devices and methods.
6. Maintenance by personnel not required to have special ability.
7. Minimum investment in spare components and replacement parts.
8. The need for demand records which would permit simple analysis for billing without requiring time-consuming manipulations on special skills, and which would eliminate any ambiguity in interpretation.

A review of available metering equipment usually employed for the measurement and automatic recording of energy and power revealed that in no one case would existing devices meet all requirements. The nearest approach would be a combination of devices furnished by several manufacturers. Such an approach was considered undesirable because of the divided responsibility for operation of the equipment and the lack of operational experience with such a combination.

A further study of the problem showed that, if certain devices which had been in use by the electric utilities of the country for approximately 30 years could be modified to meet the requirements of this particular application, most of the first-considered obstacles could be removed.

Because of the wealth of operating experience with the impulse type of power metering, it was believed that certain modifications could be made in standard devices which would then permit them to meet the requirements of this particular application. The following special features were regarded as essential if the following stipulated accuracy requirements were to be met:

1. It must be possible to record up to 1,000 impulses per demand interval. The standard device is limited to approximately 300 impulses per interval.
2. Means must be provided to store impulses during the period that the demand meter is recording and resetting to zero, in a manner to avoid positively the loss of any impulses, or the recording of an impulse in the wrong demand interval.

A co-operative study by engineers of the American Gas and Electric Service Corporation and the General Electric Company resulted in a new and in some respects unique power-metering system. With equipment designed by the General Electric Company, this system satisfactorily meets the needs of this particular application.

The system uses only existing devices and designs backed up by records of satisfactory field service over long periods, with simple, yet novel modifications to provide the high impulse rate and the impulse storage means. Fig. 1 shows its components.

Fig. 4 (right). Schematic diagram of impulse accumulator

Solution

Fig. 2 is a block diagram to illustrate functionally the high impulse demand metering system. The watt-hour meter measures energy consumption in the usual manner. To meet the requirements for sustained accuracy over the entire load range, a photoelectric contact device was designed to replace the conventional mechanical contact device. A schematic diagram of this new mechanism is shown in Fig. 3. It acts as a single-pole double-throw switch, alternately moving from one position to another in response to the rotation of the watt-hour meter rotor. A control relay is connected in the output of each switch position to provide increased energy-handling capacity. Gearing within the contact device permits preselection of the energy consumption necessary to initiate switching action.

The switching action of the control relays is arranged to generate electric impulses, each impulse representing a specific value of energy consumption. These impulses are first fed to the impulse accumulator, which is used with each printing demand meter to provide for the storage of impulses generated during the period in which the demand meter is printing and resetting to zero. Its use insures against the possibility of losing impulses, and makes possible a precise check of the total impulses generated against the total recorded by the demand meter.

The impulse accumulator is shown schematically in Fig. 4. In many respects, it is mechanically similar to the General Electric Company type *MD-4* totalizer equipped with a type *D-6* contact device, but it functions differently. An incoming impulse operates motor 1 to rotate shaft 2 through 30 degrees and, through differential gears 9 and an intermediate gear train, to rotate cam shaft 3, in order to lift brush 4 out of the slot in cam 5 and close contact 6. The closing of contact 6 energizes motor 7 which rotates shaft 8 and, through differential gears 9 and the intermediate gear train, to rotate cam shaft 3, in order to return cam 5 to its "home" position, where contact 6 opens and de-energizes motor 7. The outgoing contact device 10 is also operated by shaft 8, to generate one outgoing impulse for each incoming impulse.

To store impulses, the electrical circuit between contacts 6 and motor 7 is opened by an auxiliary switch, normally located in the contact-making clock. Incoming impulses then continue to rotate cam shaft 3, each impulse pro-

ducing a definite angular rotation. When the auxiliary switch is again closed, motor 7 remains energized until cam 5 returns to its home position at which time an outgoing impulse has been generated for each stored impulse. Stored impulses are converted into outgoing impulses at the rate of one about every 2 seconds. The mechanism permits incoming impulses to be received at the same time that outgoing impulses are being generated, without any loss of impulses.

Output impulses from the impulse accumulator are fed to the printing demand meter where they are counted and recorded in the usual manner. The need for a printing demand meter capable of accepting up to 1,000 impulses during each demand interval was met by modifying the General Electric Company type *PD-6* printing demand meter. The demand registering mechanism was redesigned to accept 999 impulses by providing additional numerals on the small type wheel and modifying the mechanism which indexes this wheel. The reset mechanism was redesigned to be operated by a continuously energized motor rather than by the storage of energy in a spring. By this means the reset torque is maintained at a constant value and reset is accomplished at a relatively constant speed, with minimum acceleration and deceleration. A further modification of the reset mechanism permits the reset operation to be accomplished with the large type wheel resetting in a maximum of one revolution. Fig. 5 illustrates the design modifications which have been made.

The special contact-making clock, a modification of the standard General Electric Company type *C-16* contact-making clock, provides the necessary switching action by means of three independent switches operated in time sequence, as shown in Fig. 6. The first switch S_1 opens at the end of the demand interval to de-energize the output mechanism of the impulse accumulator and thus shuts off the flow of impulses to the printing demand meter. (This switching action, in effect, defines the end of one demand interval and the start of the next.) Thirty seconds later, the second switch S_2 closes and sends an impulse to the demand meter, causing it to print the interval demand and to reset to zero. Sixty seconds later, the third switch S_3 closes and sends another impulse to the demand meter, causing it to print "zero" and thus provide a record that the demand meter has reset to zero. Thirty seconds later the first switch S_1 closes and re-energizes the output mechanism of the impulse accumulator. During the 2-minute period in which the output mechanism of the impulse accumulator is de-energized, all incoming impulses are stored; none is lost or counted in the wrong demand interval.

Conclusion

In conclusion, it should be emphasized that this paper illustrates the beneficial results and advancements in the metering art which can be realized through the co-operative effort of a utility and a manufacturer, wherein application requirements, design and manufacturing problems, and difficult delivery schedules were recognized as elements of a single problem. In this case through such co-operative effort special equipment was successfully provided to meet a special demand-metering application, and which has pointed the way to improved techniques for demand metering in general.

A Signal-Discriminating Magnetic Amplifier

G. E. LYNN
ASSOCIATE MEMBER AIEE

J. F. RINGELMAN
ASSOCIATE MEMBER AIEE

A NEW FIELD of application for magnetic amplifiers is promised by the development of a signal amplitude discriminator. This signal-discriminating amplifier has the unique ability to select the largest of any number of signals and to amplify the selected signal in the normal way. The mechanics of the amplifier are described in this paper and typical measured values are discussed.

Voltage Summation or Selection

In view of the many applications of magnetic amplifiers as summing devices, the existence of a magnetic phenomenon which would allow signal selection rather than summation when first considered might seem improbable. When time-varying voltages are involved, however, further thought reveals that summation of these voltages on a single magnetic reactor is really the improbable result, as will be shown.

Consider, for instance, a toroidal reactor with several windings such as is commonly used in a magnetic amplifier. If the windings are assumed to have zero resistance and if leakage flux is negligible, the volts per turn must be the same for all windings. This will be true regardless of the number or comparative magnitudes of external voltage sources included in the circuits of which the individual windings form a part. If impedances external to the reactor windings in the individual circuits are small, the volts per turn ratio will be determined by the source which supplies the highest voltage for the number of turns to which that voltage is applied. All other windings will deliver energy to their respective circuits rather than accept energy from them.

For this reason, a single-core magnetic amplifier which has several control windings to which time-varying voltages are applied will be controlled by the signal supplying the highest volts per turn ratio. If loading between windings is prevented, the other signals will not affect the operation of the amplifier.

The problem of signal selection rather than summation may be resolved into two parts:

Y., January 30–February 3, 1956. Manuscript submitted September 30, 1955; made available for printing December 7, 1955.

G. E. Lynn and J. F. Ringelman are with Westinghouse Electric Corporation, Baltimore, Md.

The authors wish to acknowledge the unpublished work of F. A. Baker, formerly with Westinghouse Electric Corporation, concerning the development of the method of impedance control described in the "Analysis of Basic Circuitry" portion of this paper.

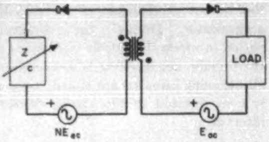

Fig. 1. Ramey-type magnetic amplifier circuit

1. Conversion of all signals to time-varying voltages of one frequency whose average value is proportional to signal amplitude.
2. Elimination of the loading between circuits when these time-varying voltages are coupled to a common magnetic reactor.

Analysis of Basic Circuitry

Ramey has described a magnetic amplifier, Fig. 1. which applies a variable volt-second integral to reset a magnetic core.[1,2] Variation of the volt-second integral is obtained by use of a variable impedance in the control circuit. Since a magnetic amplifier is itself a variable impedance, it is a simple matter to substitute the gate winding of another magnetic amplifier (of the basic half-wave type) for the control impedance of Fig. 1, as shown in Fig. 2. The load voltage E_L is now a function of the signal voltage E_s.

In explaining the operation of Fig. 1, certain simplifying assumptions will be made:

1. Cores L_1 and L_2 have flux-current loops essentially rectangular, as shown in Fig. 3.
2. Rectifiers X_1 and X_2 are ideal; i.e., zero conduction in the reverse direction and zero voltage drop in the forward direction.
3. The resistance in the windings of the reactors is negligible.
4. When applied to winding N_L, the magnitude of E_{ac} is just sufficient to drive the flux of reactor L_2 from negative to positive saturation in one half-cycle of supply frequency. Reactor L_1 is designed so that NE_{ac} will just drive flux from negative to positive saturation in one half-cycle of supply frequency.
5. The exciting current of the gate winding of reactor L_1 is negligible in comparison with the exciting current of the control winding of reactor L_2.

As a further aid to explanation, the basic impedance controlled amplifier will be broken down into three circuits:

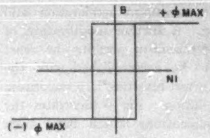

Fig. 3 (above). Idealized flux-current loop

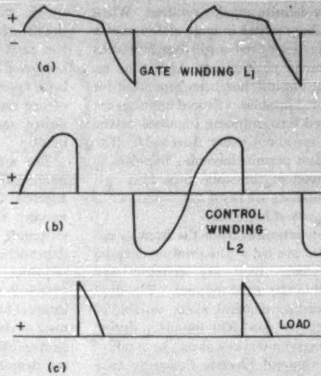

Fig. 4 (right).

a—Gate-winding voltage of reactor L_1
b—Control winding voltage of reactor L_2
c—Load voltage

1. The *signal circuit*, which consists of the series combination of:
   (*a*) Signal source E_s.
   (*b*) Total circuit resistance, R_s.
   (*c*) Control winding N_s of reactor L_1.
2. The *control circuit*, which consists of the series combination of:
   (*a*) Voltage source NE_{ac}.
   (*b*) Gate winding N_g of reactor L_1.
   (*c*) Ideal rectifier X_1.
   (*d*) Control winding N_c of reactor L_2.
3. The *load circuit*, which consists of the series combination of:
   (*a*) Voltage source E_{ac}.
   (*b*) Gate winding N_L of reactor L_2.
   (*c*) Ideal rectifier X_2.
   (*d*) Total load circuit resistance R_L.

Two distinct periods of time will be considered and will be distinguished from each other by the polarity of E_{ac}. A positive half-cycle will be defined as a half-cycle when E_{ac} tends to cause forward current through rectifier X_2. A negative half-cycle, then, is a half-cycle when NE_{ac} tends to cause forward conduction in rectifier X_1.

The reactor windings are shown dotted on one end to show relative instantaneous voltage polarities. The dotted ends of all windings on one core have the same instantaneous polarity.

In analysis, let it first be assumed that E_s is zero and the control circuit is open. Voltage E_{ac} will cause reactor L_2 to saturate on the first positive half-cycle of supply voltage. Each succeeding positive half-cycle will then appear across load resistor R_L, causing load voltage E_L to have its maximum value. If the control circuit is now closed and E_s is maintained at zero, reactor L_1 will saturate in the first negative half-cycle of supply voltage. Since it was assumed that the exciting current of the gate winding of reactor L_1 is very small compared with the exciting current of the control winding of reactor L_2, negligible voltage will appear across the control winding of reactor L_2 during a negative half-cycle until reactor L_1 saturates. Following saturation of reactor L_1, each succeeding negative half-cycle of supply voltage will cause NE_{ac} to appear across the control winding of reactor L_2. If on the positive half-cycles of supply voltage, reactor L_2 is driven from $-\phi_{max}$ to $+\phi_{max}$ by E_{ac} on the negative half-cycles it will be driven from $+\phi_{max}$ to $-\phi_{max}$ by NE_{ac}. Under these conditions, E_{ac} will appear across the gate winding for each entire positive half-cycle and no voltage will appear across R_L. This latter statement is, of course, only approximately true, since the exciting current of the gate winding of reactor L_2 will flow through R_L. Where the resistance of R_L is very small with respect to the unsaturated impedance of the gate winding, the approximation is a valid one.

It has now been shown that, by application of voltage NE_{ac} in the circuit of Fig.

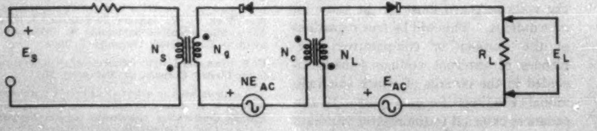

Fig. 2. Basic signal converter used with Ramey-type amplifier

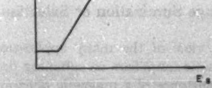

Fig. 5. Average output voltage as a function of average signal volts for circuit of Fig. 2

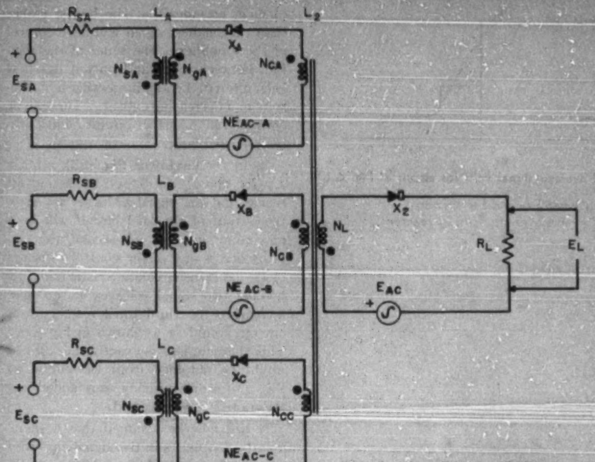

Fig. 6a. Basic signal-discriminating amplifier circuit

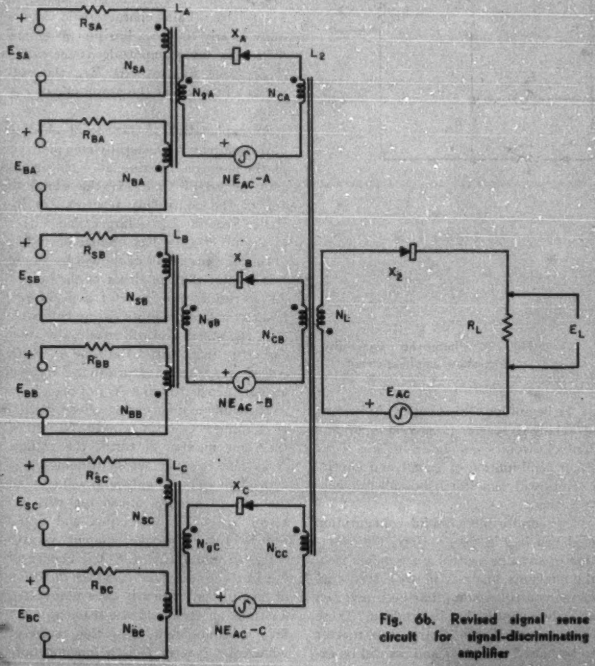

Fig. 6b. Revised signal sense circuit for signal-discriminating amplifier

2, the load voltage E_L has been changed from a maximum to essentially zero. The next step is to examine the possibilities of obtaining intermediate voltages. If a small signal voltage E_s is applied, the flux in reactor L_1 will be driven from saturation to some unsaturated condition during the positive half-cycles of supply voltage. On the negative half-cycles, NE_{ac} will appear across the gate winding of reactor L_1 until the core has absorbed sufficient volt-seconds to bring the flux back to saturation. (Integration of both sides of the expression $e=Nd\phi/dt$ shows that $(\phi_2-\phi_1)=1/N\int edt$. For a given winding, then, a change of flux in a reactor is equivalent to a volt-second area.) After saturation, NE_{ac} will appear across the control winding of reactor L_2 for the remainder of the half-cycle. Since some of the volt-second area represented by a half-cycle of NE_{ac} has already been expended in changing flux in reactor L_1, a sufficient area will not be available to change flux in reactor L_2 all the way from positive saturation to negative saturation. At the end of the negative half-cycle, therefore, the flux in reactor L_2 will be somewhere between positive and negative saturation. As a result, only a portion of the positive half-cycle volt-second area supplied by E_{ac} will be required to drive the flux in reactor L_2 back up to positive saturation. The remainder will appear across R_L after saturation is reached.

The wave shapes appearing across particular components for a typical condition are shown in Fig. 4. In Figure 4(a), the voltage appearing across the gate winding of reactor L_1 during the positive half-cycle results from the flux change during reset. The shape of this voltage is a function of the impedance and net voltage of the control circuit as well as the magnitude and shape of the signal voltage and the signal circuit impedance. The wave shape shown is for a small d-c signal and a moderately high signal circuit impedance. Fig. 4(b) indicates that NE_{ac} appears across the terminals of the control winding N_c for some portion of the negative half-cycle and that an equal voltage is induced on the control winding during the positive half-cycle by application of E_{ac}. Fig. 4(c) illustrates the wave shape across the load resistor R_L.

If the signal voltage E_s is sufficiently large, the flux in reactor L_1 will be driven to negative saturation during its reset half-cycle. NE_{ac}, then, will appear across reactor L_1 for the entire negative half-cycle and no voltage will appear across the control winding of reactor L_2

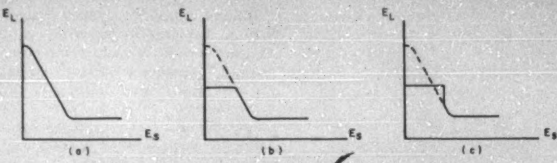

Fig. 7. Average output voltage as a function of average signal volts for circuit of Fig. 6(b)

a—Characteristic obtained with reactor L_A when E_{SB} and E_{SC} are zero

c—Discontinuity due to coupling effects

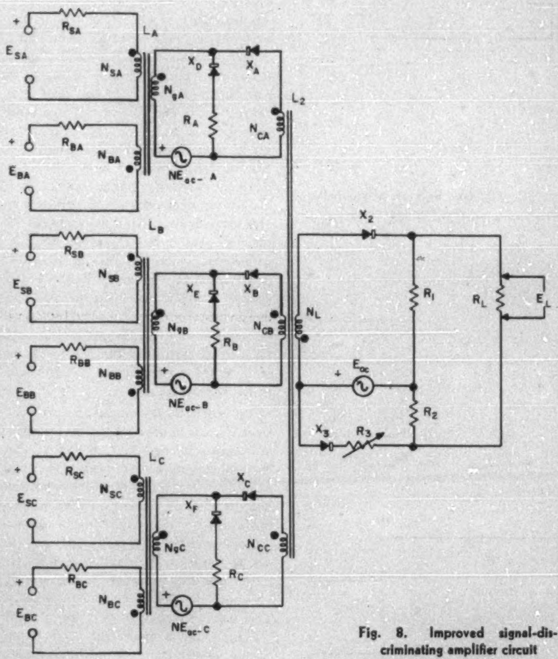

Fig. 8. Improved signal-discriminating amplifier circuit

during that time. Under these conditions, E_{ac} will appear across the load for the entire positive half-cycle. Thus, the signal voltage can control the load voltage from zero to maximum, as shown on the transfer characterictic of Fig. 5.

The Signal-Discriminating Amplifier

It has now been shown that, by the use of reactor L_1, a signal can be converted into a time-varying voltage. The first half of the 2-part problem mentioned at the beginning of this paper is solved by attaching to reactor L_2 several signal and control circuits, as shown in Fig. 6(a). Each combination of signal and control circuits will henceforth be called a control stage.

A generally more useful configuration is shown in Fig. 6(b). Here, the operation of any one control stage differs from the previous analysis in that the sense of the control winding has been reversed and a bias winding has been added. These changes permit each control stage reactor to be biased to cut off and, as will be explained, provides that the largest rather than the smallest signal will have control of the amplifier. The sense of the relation between input and output has now been altered; i.e., an increasing signal results in a decreasing output. This can be corrected by a further circuit addition to be discussed later.

If, in the circuit of Fig. 6(b), reactor L_A, L_B, and L_C are biased to the cut off region and the signal voltages are zero, the output of the load circuit will be a maximum since no volt-second area appears across any of the control windings of L_2. A transfer characteristic taken by holding two signal voltages at zero and increasing the third until reactor L_2 is cut off, would be as shown in Fig. 7(a). This characteristic is exactly the same as would be obtained from the circuit of Fig. 2, if a bias winding were added and the control sense reversed.

It will now be assumed that a signal voltage E_{SA} exists in the signal circuit of reactor L_A of sufficient magnitude to cause an output voltage E_L, of about one half the maximum shown in Fig. 7(a). Increasing the signal voltage E_{SB} of reactor L_B from zero to maximum results in the transfer characteristic shown in Fig. 7(b). This characteristic shows quite clearly that E_{SB} has no effect until it has the same amplitude as the signal E_{SA}. Once E_{SB} exceeds E_{SA}, the output is a function of the amplitude of E_{SB} only.

An explanation of this signal-selecting operation requires a step-by-step analysis of the voltages existing at each significant period of time. If the signal to one of the controlling reactors, for instance reactor L_A, is larger than either of the others, the flux change occurring during the reset half-cycle will be less in this reactor than in either of the others. As a result, this reactor will absorb fewer volt-seconds in its gating half-cycle than the others and will reach saturation earlier in time. After the time at which reactor L_A reaches saturation, $NE_{ac}-A$ appears across winding N_{CA} of reactor L_2 in the same manner as described earlier. If windings N_{CA}, N_{CB}, and N_{CC} have the same number of turns, the voltage NE_{ac} also appears across windings N_{CB} and N_{CC}. These induced voltages in the control circuits associated with reactors L_B and L_C are equal and opposite to the respective source voltages $NE_{ac}-B$ and $NE_{ac}-C$. The change of flux in reactors L_B and L_C in the direction of positive saturation is thus terminated for this half-cycle and the reactors never fire. It is apparent, then, that the reset voltage for reactor L_2 is a function only

Vol. 7
Pt. 1
1956

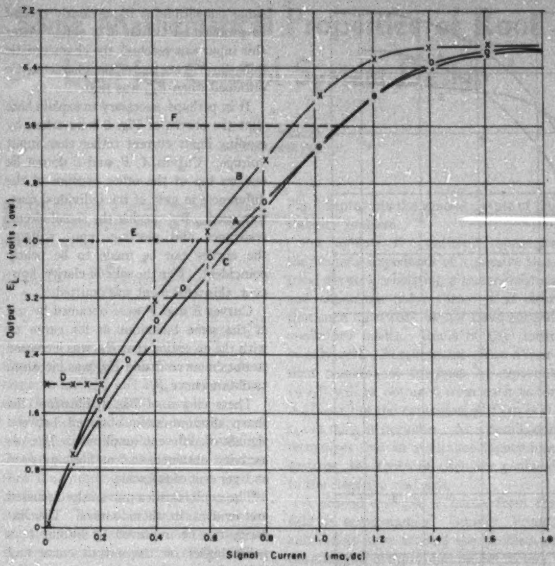

Fig. 9. Individual and combined transfer characteristics of the signal-discriminating amplifier shown in Fig. 8

of the control circuit associated with reactor L_A and, hence, the output voltage E_L is a function only of the signal E_{SA}.

It will be assumed, for the moment, that the flux levels existing in reactors L_B and L_C at the start of a negative half-cycle are a function exclusively of the signal voltages E_{SB} and E_{SC}. With this assumption in mind, it can be seen that, as some other signal voltage, for instance that of reactor L_B, is increased, the theoretical firing angle will decrease in the associated gate circuit until it is finally less than the actual firing angle of reactor L_A. When the theoretical firing angle is less than that of the reactor which had been in control, reactor L_B will gain control of L_4 and decrease the output voltage as shown in Fig. 7(b).

EFFECTS OF NONIDEAL CONDITIONS

There exists one most significant departure in the actual operating circuit from the simplifying assumptions stated before. In reality, the flux reset levels of reactors L_A, L_B, and L_C are dependent not only on their respective bias and control currents but upon the difference in their firing times. If it is assumed, for instance, that the signal to reactor L_A is slightly greater than the signals to reactors L_B and L_C, then, after firing of L_A, a voltage equal to $NE_{ac}-A$ will appear across control winding N_{CB} as previously discussed. (The effects on reactor L_C will be the same as for reactor L_B. For the sake of brevity, only reactor L_B will be discussed.) With the appearance of this voltage across N_{CB}, flux change in reactor L_B in the positive direction will cease. This follows from the fact that voltage $NE_{ac}-B$ and the voltage induced on N_{CB} are equal and opposite, resulting in a net voltage of zero.

At the moment that the net voltage becomes zero, flux reset begins in reactor L_B under the net influence of the bias and signal voltages. It is important to note that this reset action starts during a gating half-cycle. Flux reset does not occur instantaneously, but requires a definite length of time to proceed to completion. The time required is a function of the circuitry involved. Under the conditions imposed by the circuit of Fig. 6, reset which starts at the beginning of a reset half-cycle is interrupted by the start of the next gating half-cycle. This can be seen in the wave shape of Fig. 4(a). This indicates that, given more time, a larger flux change would have been achieved. When reset starts in the gating half-cycle, as in the case under discussion, more time is allowed for reset and a larger flux change actually is achieved.

An interaction now exists between reactors L_A and L_B. If reactor L_A had not fired, the gating half-cycle of reactor L_B would not have been interrupted and the flux level in reactor L_B would have been higher at the start of the next gating half-cycle.

For a given signal amplitude, then, at least two flux levels are possible in reactor L_B at the start of its gating half-cycle. One is obtained when reactor L_A does not fire first, the other when reactor L_A has fired first. When the signal E_{SB} is increased until reactor L_B takes over control, there is an abrupt transition from the latter condition to the former. This transition results in a discontinuity in the amplifier transfer characteristics similar to that shown in Fig. 7(c).

The addition of a rectifier and a resistor to each control circuit, as shown in Fig. 8, overcomes this deficiency. Now, if reactor L_A is in control, when reactor L_A fires a voltage equal to $NE_{ac}-A$ will appear across control windings N_{bB} and N_{CC} as before. In the control circuit associated with reactor L_B, this voltage will no longer prevent current flow in the gate winding N_{gB}. The voltage rise around the circuit formed by $NE_{ac}-B$, winding N_{gB}, X_B, and R_B remains $NE_{ac}-B$. Reactor L_B is now allowed to saturate in its gating half-cycle and the flux level existing at the start of a gating half-cycle is a function only of signal E_{SB}. The dependence upon the amplitudes of the other signals has been eliminated.

In the foregoing analysis, the effects of reverse leakage and forward drop in the diodes have been ignored. By using silicon diodes it is possible to obtain leakage currents so low that they properly may be dismissed. The problem of forward drop, however, remains. As a result of this drop, the voltage appearing across the control windings of reactor L_1 after one of the controlling reactors has fired is not NE_{ac}, but is smaller by the amount of instantaneous voltage appearing across diode X_A, X_B, or X_C. In designing the reactors for the circuit of Fig. 8, the effect of forward drop is considered only when calculating the number of turns to be wound on reactor L_2. In the circuit of Fig. 6, however, the effect of forward drop of the controlling circuit diode may be to allow flux change in reactors L_B and L_C to continue after reactor L_A has fired, although at a much slower rate. For this reason, the magnitude of the discontinuity encountered with this circuit may vary.

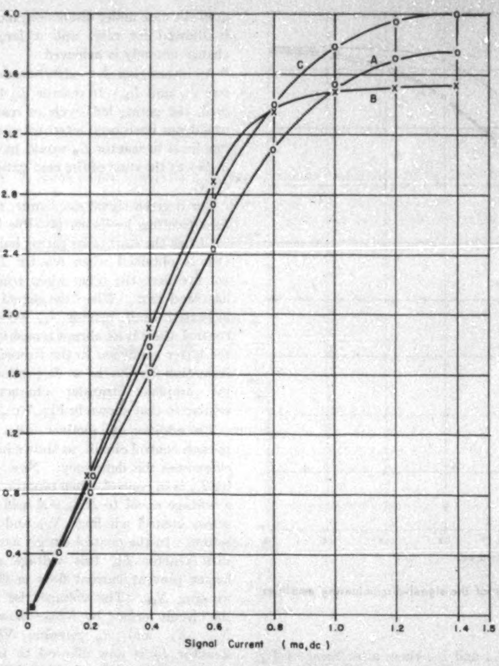

Fig. 10. Individual transfer characteristics of the signal-discriminating amplifier with bias point shifted to improve linearity

A departure from ideal conditions which is less amenable to solution is a nonlinearity in the transfer characteristic inherent in the circuit of Fig. 2. It apparently arises from the effect, on reset of the controlling reactors, of the variation of the net voltage rise around their gating circuits during their reset half-cycle. The effect, on an amplifier's reset characteristics, of the voltage applied to the gate winding of a half-wave magnetic amplifier during the reset half-cycle is discussed by Roberts, Huhta, and others.[3,4] In the circuit of Fig. 2, this effect is complicated by the fact that the voltage seen by the reactor is not constant but is a function of the firing angle of reactor L_2. Attempts to remove or decrease this effect by the use of switching transistors to replace diodes X_A, X_B, and X_C have not been entirely successful at the time of writing.[5] The nonlinearities can be removed from the circuit of Fig. 2 by this method, but when applied to the circuit of Fig. 8, a small interaction between signal voltages becomes apparent in the transfer characteristics (not shown).

EXPERIMENTAL RESULTS

Transfer characteristics obtained from the signal-discriminating magnetic amplifier circuit of Fig. 8 are shown in Fig. 9. To reverse the characteristic of Fig. 7 and allow proper sensing of input and output (zero output for zero signal), resistors R_1, R_2, and R_3, and diode X_3 have been added to the load circuit, as shown.

The curves of Fig. 9 were obtained in the following manner. With all signal voltages zero at the start, each signal in turn was increased to a maximum in small increments and returned to zero, while readings of input and output were taken at each step in the usual manner. These readings are plotted as curves *A*, *B*, and *C*, corresponding to signal voltages E_{SA}, E_{SB}, and E_{SC}, respectively. Load voltage E_L was then increased to 2 volts by increasing E_{SA} to the proper magnitude. Voltage E_{SB} was then increased in small increments until an output voltage of 4 volts was reached. These points are plotted as curve *D*. Note that the output was constant until E_{SB} reached the same magnitude as it previously needed to produce an output of 2 volts. After this input was reached, the characteristic falls directly on top of the characteristic obtained when E_{SA} was zero.

It is, perhaps, necessary to explain here that the curves of Fig. 9 were taken by reading input current rather than input voltage. Curves *A*, *B*, and *C* do not lie one on top of the other because of the differences in gain of the individual reactors used. By varying the signal circuit resistance and plotting input voltage, the curves can be made to be nearly coincident. For the sake of clarity, however, this refinement was omitted.

Curves *E* and *F* were obtained by use of the same technique as for curve *D*, with the exception that E_{SC} was increased to obtain curve *E* and E_{SA} was increased to obtain curve *F*.

These curves of Fig. 9 illustrate the sharp discrimination obtained between signals of different amplitude. The selectivity obtained was at least as good as 1 per cent of full scale.

The nonlinearities previously discussed are evident in these curves. The linearity can be improved by biasing to a point higher on the output curve and balancing out the resulting output voltage by changing the value of resistor R_3. Fig. 10 shows curves obtained by use of this method, yielding a linearity of about 2 per cent of full scale.

Conclusion

A circuit capable of discriminating between signals of different amplitudes has been presented. The circuit is not limited to either a-c or d-c signals, but operates equally well with either or both. It responds to the average value of a signal and will compare this value with the average of some other signal. A circuit of this type can readily find application in protection devices, telemetering, and other fields.

Some Mathematical Properties of Root Loci for Control System Design

F. M. REZA
NONMEMBER AIEE

IN the study of a linear lumped system one is confronted with a linear differential equation

$$a_0i+a_1\frac{di}{dt}+\ldots a_n\frac{d^ni}{dt^n}=b_0e+b_1\frac{de}{dt}+\ldots b_m\frac{d^me}{dt^m} \quad (1)$$

where the applied stimulus and system response are $e(t)$ and $i(t)$, or vice versa, and t is the independent variable.

When one is dealing with physical systems, either the physical realizability or the stability of the system requires that the transient response of a system with loss vanish for a vanishing applied stimulus. This characterization somewhat restricts the location of the roots of the characteristic equation of the differential equation of the system. Indeed, if one uses operational methods, the transient and steady-state solutions of the system, equation 1, will be described by equation 2

$$\frac{E}{I}=\frac{P(s)}{Q(s)}=\frac{a_0+a_1s+\ldots a_ns^n}{b_0+b_1s+\ldots b_ms^m} \quad (2)$$

where $s = \sigma + j\omega$ is a complex variable. A general restriction on the system could be expressed conveniently as a restriction on the location of roots of the polynomials $P(s)$ and $Q(s)$.

The first task in this work is to realize the fact that the general problem of the stability of linear systems depends upon the study of a fundamental problem of mathematics, namely, knowledge of the approximate location of the roots of a polynomial in a region of the complex plane, and the loci of these roots as functions of the coefficients of that polynomial. Fig. 1 represents the general nature of the stability problem.

For instance, if equation 2 represents the transfer impedance of a passive electrical network consisting of linear resistors and capacitors only, then it is clear that such a network cannot have natural oscillatory modes. Roots of $Q(s)$ must be only real. Furthermore, since a transient response of the form A_k exponent $(+s_kt)$ will be obtained from each factor $A_k/(s-s_k)$ of the expansion of $P(s)/Q(s)$, s_k can only be negative. As a result, one recognizes that in resistance-capacitance systems, the roots of $Q(s)$ are confined to the negative real axis.

A second example is taken from the field of aerodynamics. Gunder, Friant, and others have studied the problem of the chugging of liquid-fuel rocket motors.[1] A rocket motor is stable (chug-free) if, and only if, none of the roots of

$$s^2+Ms+N+\epsilon^{-s}(Ls+T)=0 \quad (3)$$

are in the right-half s-plane (with some restriction for roots on the axis of imaginaries); M, N, L, and T are numerical coefficients depending on the system under consideration.[2] In the study of such problems, one is interested to find the loci of the roots of this equation while one or more of the coefficients is varying.

A third example is taken from a more recent field, namely, the linear programming of digital computers. The transfer function of a linear real-time program is generally expressed as

$$W(s)=\frac{a_0+a_1\epsilon^{-Ts}+a_2\epsilon^{-2Ts}+\ldots+a_n\epsilon^{-nTs}}{b_0+b_1\epsilon^{-Ts}+b_2\epsilon^{-2Ts}+\ldots+b_m\epsilon^{-mTs}} \quad (4)$$

A transformation of the exponential type

$$z=\epsilon^{-Ts} \quad (5)$$

leads back to the familiar field of the rational fractions

$$W(z)=\frac{a_0+a_1z+a_2z^2+\ldots+a_nz^n}{b_0+b_1z+b_2z^2+\ldots+b_mz^m} \quad (6)$$

The stability of the system requires that all the roots of the denominator of equation 6 remain outside the unit circle of the z-plane. Roots on the unit circle may not be multiple.[5,6]

Although a number of classical tests are available to determine whether a polynomial has all its roots within the unit circle, still a deeper insight into the problem is desirable. It is of greater interest to obtain a priori knowledge of the whereabouts of the roots without being engaged in the numerical solution of these equations. Having this in mind one is naturally led to the study of certain potential curves which curves are the topic of this paper.

From the previous examples, it is concluded that a discussion of the stability of a lumped linear system can be translated mathematically into the following problem: Study of the relative location of the roots of a polynomial in a region of the complex plane.

The first objective in this section of the paper is to unify the aforementioned two well-known problems of stability and root locus. Indeed, it is unfortunate that study of the polynomials and rational fractions such as referred to in the text and the comprehensive bibliographies of references 5 and 6 has rarely been made by engineers dealing with control problems. It is also essential to estimate the complexity of an engineering problem in this field by first translating it into mathematical terms where more tools are available.

In most engineering problems of this kind, the engineer's work is not fully done by simply guaranteeing the confinement of the roots of a polynomial to a domain as a simple application of Routh or similar criteria. A physical system usually contains a number of parameters; moreover, the characteristics of the involved elements such as vacuum tubes, springs, etc., vary with time. Some knowledge of the relative position of the roots in the frequency domain is extremely valuable. In this respect, some engineering methods devised for this problem in the last decade form an addition to the well-known earlier classical work on stability. As an example, consider the stability of a system with a feedback loop; see Fig. 2. The stability of the system requires that all poles of $W(s)$ remain in the left-half s-plane.

$$W(s)=\frac{k_1Z(s)}{1+k_1k_2Z(s)}=\frac{k_1P(s)}{Q(s)+k_1k_2P(s)} \quad (7)$$

where $Z(s)=P(s)/Q(s)$. As k_1k_2 is varied one may study the loci of the roots of

$$Q(s)+k_1k_2P(s)=0 \quad (8)$$

These are the curves which may be called "root loci." Evans, who is largely responsible for the use of root locus in

Y., January 30–February 3, 1956. Manuscript submitted October 24, 1955; made available for printing December 14, 1955.

F. M. Reza is with Syracuse University, Syracuse, N. Y.

The author wishes to thank Prof. J. L. Walsh of the Mathematics Department of Harvard University, who is a well-known authority on potential curves and related topics, for his stimulating discussion and advice; Dr. W. R. LePage of Syracuse University, and Dr. W. W. Seifert of the Dynamic Analysis and Control Laboratory at Massachusetts Institute of Technology for reading the manuscript.

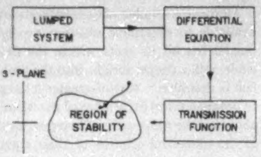

Fig. 1. General nature of the stability problem

servomechanisms, suggests the merit of the study of the root locus in control problems. He gives a number of very interesting examples of application; however, he does not describe or discuss the geometry of these curves.[7–] In the second section for the convenience of the reader is given a summary of the practical methods of finding root loci. Fig. 3 represents an example of the root-locus problem.

The second objective, in the third section of the paper, is the study of the generalized root locus curves pertaining to a polynomial $P(s)=k$, when k is a variable parameter. $Q(s)$ and $P(s)$ could be polynomials with real or complex coefficients; k may also be a complex parameter. At this stage it is unimportant that such systems are or are not of immediate engineering value. The aim is to attack a problem of mathematical physics in its utmost generality.

The fourth section is similar to the third with the exception that it deals with root locus pertaining to rational fractions.

In the fifth section is presented a unified picture of the root locus and well-known potential curves. Most of the mathematical developments of the topic were already known before the end of the last century, but apparently they have not been fully exploited for engineering purposes. In fact, the engineering literature pertaining to the subject seldom mentions this mathematical connection, and most of the properties already known to the mathematical physicists of the 19th century, such as Briot, Bouquet, Gauss, Klein, Lamé, and Maxwell, are being rediscovered for their engineering use. Undoubtedly the recent engineering literature of the subject is of great assistance in the design of servo control systems. Nonetheless it is felt that the connection of these studies with our classical background has not been fully discussed elsewhere. In this respect it is hoped that this paper will revive some interest in classical sources as a basis for further exploration and application of control problems.

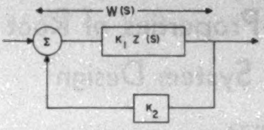

Fig. 2. General single-loop feedback system

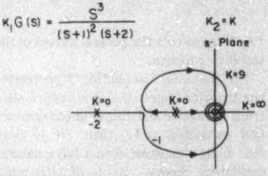

Fig. 3. Example of root-locus problem

Summary of Root-Locus Methods

At present the root-locus methods deal only with the case of a sinlge-loop feedback with real gain factors and real transfer functions using the common notation.

$$1+kG(s)=0 \tag{9}$$

Root locus is defined as the locus of roots at equation 9 when k varies from zero to infinity. Bollay[10] and Yeh[11] summarize the properties of the root-locus curve in the following:

1. A branch of root locus starts from an open-loop pole where $k=0$ and terminates at an open-loop zero where $k=\infty$.
2. The root locus of a real system is always symmetrical about the real axis.
3. The system will become unstable when root locus enters the right-half plane.
4. For a realizable transfer function $G(s)$ there are as many root-loci branches as the number of poles of $G(s)$. If the numerator and denominator of $G(s)$ are respectively of degree m and n, there are n-m zeros of $G(s)$ located at infinity, hence n-m branches terminating at infinity.
5. The asymptotic center is the intersection point of all linear asymptotes. For a real system this point is on the real axis

$$\sigma_\infty=\frac{\sum_{r=1}^{n}p_r-\sum_{r=1}^{m}z_r}{n-m} \tag{10}$$

p_r being a pole and z_r a zero of $G(s)$.

6. At a junction point the tangents to the locus are equally spaced over 2π radians.

Property 1 is evident; properties 2 and 3 are rather obvious since they refer to real systems. Property 4 is derived from property 1 by observing that a rational function has an equal number of poles and zeros. Property 5 is derived by observing the behavior of equation 11 when s goes to infinity

$$k\left(s^m+\sum_1^m z_r s^{m-1}+\ldots+\prod_1^m z_r\right)-\left(s^n+\sum_1^n p_r s^{n-1}+\ldots\prod_1^n p_r\right)=0 \tag{11}$$

Example: consider

$$G(s)=\frac{s^3}{(s+1)^2(s+2)}$$

$$1+kG(s)=0 \qquad 0<k<\infty$$

$$\text{or } G(s)=-\frac{1}{k}$$

Following rule 4, the locus has three branches, none terminating at infinity. Based on rule 1, the three branches of locus start from −1, −1, and −2. They terminate at 0, 0, 0. A part of the real axis is included in the locus. Rule 6 gives the 90-degree angle at the junction point −3/2 and 120-degree angles at zero.

To find the breakaway point at −3/2, give an incremental change to an exploratory point in the s-plane about the real axis; see Fig. 4.

$$\text{arg of } G(s)=\text{arg}-\frac{1}{k}=-180°$$

$$\alpha+2\beta-3\gamma=-190°$$

$$\frac{\Delta h}{x}-2\frac{\Delta h}{1-x}+3\frac{\Delta h}{2-x}=0$$

$$x=\frac{1}{2}$$

For $0<k\leq 9$ the system is stable and for $k>9$ two roots enter the right-half plane and the system becomes unstable.

This gives a brief idea of a practical method of finding root locus. Other interesting rules have been devised by servo engineers, which are very useful on account of their engineering applications; see for example the work of Evans.[7–9] The object of the next section is to provide a deeper mathematical insight to these methods. It should be noted that the aim is simply to provide the research scientist in the field of control with the mathematical foundation of the problem and to relate this problem to other problems of mathematical physics. It is not the purpose of this paper to provide immediately applicable methods for the application engineer.

General Properties of Root-Locus Curves

Polynomial Root Locus

Consider an algebraic polynomial of degree p, $P(s)$ in the complex variable s; the coefficients of $P(s)$ may be real or

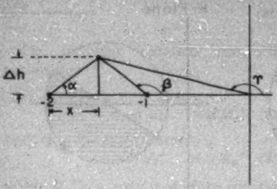

Fig. 4 (left). Determination of junction point

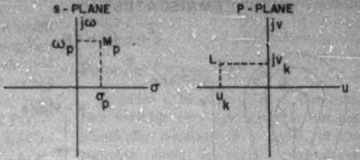

Fig. 5 (right). Conformal correspondence between s and P plane

complex numbers. To a point M_p of the s-plane with the co-ordinate $s_p=\sigma_p+j\omega_p$, there corresponds a point L in the P-plane see Fig. 5. Conversely, to each point L of the P-plane with co-ordinate $k=u_k+jv_k$, there shall correspond a number of points M_p in the s-plane which represent the roots of the polynomial

$$P(s)=k \tag{12}$$

The relation, equation 12, defines a conformal transformation between points of s-plane and p-plane. The root-locus curve is the locus of all root points (M_p) when L describes a given contour of the P-plane.

If roots points M_1, M_2, . . . M_p correspond to a point L with co-ordinate k, when L is moved to location L' with co-ordinate k', the root points take a new position M_1', M_2', . . . M_p'. The following relations are self-evident.

$$(s-s_1)(s-s_2)\ldots(s-s_p)=P(s)-k \tag{13}$$

$$(s-s_1')(s-s_2')\ldots(s-s_p')=P(s)-k' \tag{14}$$

s_k being the co-ordinate of a root point of equation 13 and s_k', the co-ordinate of a root point of equation 14. One concludes that if a variable point of the s-plane assumes the value of a root point, say s_1', then

$$(s_1'-s_1)(s_1'-s_2)\ldots(s_1'-s_p)=P(s_1')-k=k'-k \tag{15}$$

This relation can be very valuable in connection with root-locus problems. Once a set of root points is known, this relation reveals the approximate location for a root s_1' when k is changed slightly. For this purpose, one has merely to observe the approximate magnitude and argument of M_1M_1'. This is shown in the following general theorem.

Theorem 1

If $|M_k|$ represents the root points of a polynomial, $P(s)=k$ for a given value of k. When the value of k is changed to k', the points of the corresponding root locus satisfy

$$\prod_{k=1}^{k=p}\overline{MM_k}=|k'-k|=\overline{LL'} \tag{16}$$

$$\sum_{k=1}^{k=p} MM_k\sigma=\arg(k'-k)=L'Lu \pm \text{multiple of } 2\pi \tag{17}$$

$\overline{MM_k}$ and $MM_k\sigma$ stand respectively for the magnitude and argument (arg) of MM_k, σ being the point at infinity of the positive real axis.

Now that a general relation between the two sets of points of the two planes is established, a particular path must be assigned in the k-plane and the corresponding root locus found in the s-plane. Logically, and also from an engineering viewpoint, interest is mostly in two kinds of contours: infinitesimal path and linear path.

When such studies are conducted, the next logical step is to consider transformation of the infinite contour, as dual of an infinitesimal contour, and a circular path for point k as the orthogonal contour to the linear path. In brief, a mathematical treatment of the subject should use the following root locus corresponding to:

1. An infinitesimal k-contour.
2. An infinitely large k-contour.
3. A circular k-path.
4. A linear k-path.

ROOT LOCUS CORRESPONDING TO INFINITESIMAL K-CONTOUR

In many engineering problems, the point L might move along an infinitesimal contour, say, small changes in the gain of amplifiers or other devices. By the use of theorem 1, it is easy to show that the root-locus curve must form a closed loop around the corresponding root. For a deeper insight into the problem, one may assume that a root point s will move to a location $s+z$ for small change of k.

$$P(s+z)=k+\Delta k \tag{18}$$

Expansion of $P(s+z)$ gives

$$P'(s)z+P''(s)\frac{z^2}{1.2}+\ldots P^{(p)}(s)\frac{z^p}{p!}=\Delta k \tag{19}$$

If $P'(s)\neq 0$, then z also must be infinitesimal. When a point L on the P-plane is close to a location $P'(s)=0$, then

$$z^2\cong\frac{2\Delta k}{P''(s)} \tag{20}$$

Again, the root locus is infinitesimal, but certain topological changes are in sight. This analysis could be further elaborated by theorem 2.

Theorem 2

1. When the point L' moves around a contour which does not include a point corresponding to $dP^{(k)}(s)/ds^k=0$, $k=1, 2, \ldots k$, then the root loci consist of p separate closed curves around root points s_k.
2. When the contour followed by point L' is expanded to include a point L_0 so that

$$\left.\frac{dP^{(k)}(s)}{ds^{(k)}}\right|_{\text{for } s=s_0}=0,\ P(s_0)=k_0 \tag{21}$$

then $k+1$ root loci will be unified in one closed curve.

Without further elaboration on this theorem at present, the importance should be pointed out of focusing general attention on the use of the derivative in allied problems. The author has found it important to consider the notion of derivative in the system analysis and synthesis. Some other instances where interesting results are obtained from the use of the derivative are given by Reza.[13]

ROOT LOCUS CORRESPONDING TO AN INFINITELY LARGE K-CONTOUR

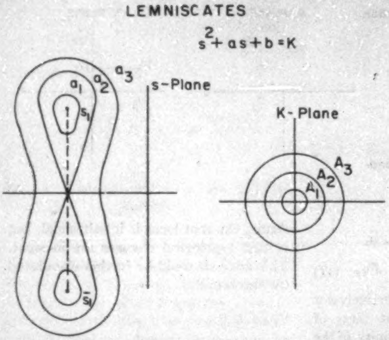
Equation 16 shows that when $\overline{LL'}$ becomes exceedingly large, $\overline{MM_k}$ must also become large. All roots of equation 14 become very large. If units masses are assigned to the roots of equation 12, the center of the gravity G of this system is such that permits the following relations for a point L' far away.

$$\overline{MG}^p=\overline{LL'};\ \text{for } \overline{LL'} \text{ large} \tag{22}$$

$$p\times MG\sigma=LL'u \pm \text{multiples of } 2\pi \tag{23}$$

Equations 22 and 23 are immediately derived from equations 16 and 17 by geometrical consideration. An analytical treatment is also easy to achieve.[8]

It is to be noted that the root points corresponding to $k=\infty$ are the vertices of a p-sided regular polygon; thus, the root loci curves have p real asymptotes symmetrically located about the center of gravity of the roots of equation 12.



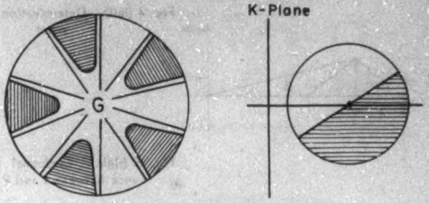


Fig. 6 (left). Example of lemniscates

Fig. 7 (above). A starshaped root-locus

Root Locus Corresponding to Circular k-Path: Cassinians and Lemniscates

In analytical geometry a Cassinian oval is described as the locus of a point which moves in a plane so that the product of its distances from two fixed points of the same plane remains constant. For a moment, assume equation 12 to be of second degree and with real coefficients

$$|(s-s_1)(s-\bar{s}_1)|=|k| \tag{24}$$

From the previous discussion, it becomes evident that for small values of $|k|$, the root loci are two small curves around s_1 and $\bar{s}_1$, and for large values of $|k|$, the root loci become unified in one large contour. The transition from two to one contour starts at a value k_0 which corresponds to s_0, the root of the derivative of equation 24

$$\left.|(s-s_1)(s-\bar{s}_1)|\right|_{s_0=s} = \left|\frac{(s_1-\bar{s}_1)^2}{4}\right| \tag{25}$$

Fig. 6 reveals these considerations (For more detailed discussion as well as the generalization, references 13 and 14 may be consulted.) To turn back to the general equation, equation 12 it is found that the root locus for $|k|$=constant is a generalized Cassinian. These curves are called lemniscates.

$$|P(s)|=|s-s_1|\,|s-s_2|\ldots|s-s_p|=\text{constant}=|k| \tag{26}$$

Some of the properties of these curves have already been discussed; to add a few remarks it may be noted that the branches of one locus or two root loci usually do not intersect. Indeed, for a common point on the two curves, there should be

$$P(s_0)=|k_1| \tag{27}$$
$$P(s_0)=|k_2|$$

except for a multiple point of $P(s)$. For such a point, naturally, two or more branches intersect. It can be shown that for small values of $|k|$, root loci consist of p mutually disjoint branches. Each branch consisting of a Jordan curve around a root point corresponding to $k=0$ (see reference 6, chapter 11). For further discussion, reference 15 may be of interest.

Root Locus Corresponding to a Linear k-Path: Stelloide or Star-Shaped Root Locus

In many problems, it is of interest to find the root locus corresponding to a straight line of the P-plane. Such curves have been called by Lucas "stelloides" (see reference 16, page 17), or star-shaped. The equation of such a curve is given by

$$\arg|P(s)|=\arg k=\text{constant} \tag{28}$$

A star-shaped curve has p hyperbolic branches which are asymptotic to the same previously mentioned asymptote lines. As point L of the P-plane approaches infinity, the root points approach the vertices of a p-sided polygon. When point L moves on the same line but in the opposite direction, the root points thus approach infinity but in directions which form$\sqcap/p$ degrees with the previous asymptotes. Fig. 7 shows such a configuration for a general fifth-degree polynomial. G is the center of gravity of unit masses located at the root points of $P(s)=0$. When the straight line of the P-plane passes through a point L_0, which corresponds to a point s_0 where

$$P^{(n)}(s_0)=0, \quad P(s_0)=k_0 \tag{29}$$

then $n+1$ branches of the root loci will be unified in one branch. This incident is similar to one already discussed for Cassinian curves.

In most engineering problems, a polynomial $P(s)$ with real coefficients must be considered. In such problem k is also generally real and the root locus will correspond to $\arg|P(s)|=0$.

For cases where $P'(s)$ has no real roots, then there are p-1 values of k such that every two are complex conjugates. P-plane will have $(p$-$1)/2$ such points in the upper half-plane and $(p-1)/2$ in the lower. The star-shaped root locus will look like a generalization of Fig. 6. Each half of the P-plane is transformed in $(p+1)/2$ contours, and these $p+1$ contours cover the whole s-plane. In Fig. 6, a large circle was drawn in the p-plane, which is transformed into a large lemniscate (looking like a circle) in the s-plane. It is evident that the lemniscate and star-shaped family of curves considered here form an orthogonal family.

Root Locus for Rational Fractions

In many engineering problems, one is dealing with a system function which appears as a rational fraction $P(s)/Q(s)$

$$\frac{P(s)}{Q(s)}=k \tag{30}$$

As in the third section, consider equation 30 defining as a conformal relationship between points of two planes. Since the trend of the discussion has already been outlined in that section similar detailed discussion may be omitted. The root locus corresponding to a circle of the k-plane will now be studied.

Cyclides

What is the geometric nature of the locus of the roots of equation 30 when point L moves on a circle? To answer this question, a circle of the P-plane may be defined as the locus of points for which the ratio of the distances to two given points L_1 and L_2 is constant

$$\frac{\overline{LL_1}}{\overline{LL_2}}=\text{constant} \tag{31}$$

The following equations are self-explanatory

$$P(s)-k_1Q(s)=MM_1'\times MM_2'\times MM_3'\ldots\times MM_p' \tag{32}$$

$$P(s)-k_2Q(s)=MM_1''\times MM_2''\times MM_3''\ldots\times MM_p'' \tag{33}$$

where M_p' is a point root of the equation 30 for $k=k_1$ and M_p'' a point root of equation 30 for $k=k_2$.

The ratio of these two equations gives

$$\frac{P(s)-k_1Q(s)}{P(s)-k_2Q(s)}=\frac{\dfrac{P(s)}{Q(s)}-k_1}{\dfrac{P(s)}{Q(s)}-k_2} \tag{34}$$

If a point L of the P-plane moves on a circle, equation 31, then $|(k-k_1)/(k-k_2)|$ remains constant, or

$$\frac{MM_1'\times MM_2'\ldots\times MM_p'}{MM_1''\times MM_2''\ldots\times MM_p''}=\left|\frac{k-k_1}{k-k_2}\right|=\text{constant} \tag{35}$$

This is the well-known geometrical property of "cyclides" which was extensively discussed in the 19th century by Darboux, Lucas, Maxwell, and others.[16,17,18]

We may choose another property of the P-plane curve and translate it into property of cyclides. In fact, a circle of the P-plane could be also considered as the locus of points L so that the angle L_1LL_2 remains unchanged.

$$L_1LL_2=\arg(k-k_1)-\arg(k-k_2)=\text{constant} \tag{36}$$

or

$$M_1'MM_1''+M_2'MM_2''+\ldots M_p'MM_p''=\text{constant} \tag{37}$$

Equations 35 and 37 are known to those in the field of servo control by magnitude and angle criteria. The engineering applicarion of these two relations is based on the fact that if a point root is considered, say, close to M_1', then for small variation of k, all the magnitudes encountered in equation 35 remain practically unchanged with the exception of one. A similar statement could be made for the arguments involved in relation 37.

Root Locus Corresponding to Small Variation of k

By an expansion similar to equation 19 it may be shown that if $|P(s)/Q(s)|'\neq 0$ about the points of the root locus corresponding to $k+\Delta k$, then all roots must move infinitesimally. As a result theorem 3 may be stated.

Theorem 3

When a point L moves about a small contour in the P-plane containing no point L_0 corresponding to a critical point of $P(s)/Q(s)$, the root-locus curves consist of a p small, closed curves, each containing only one of the roots of $P(s)-k_1Q(s)=0$. (In the P-plane circle k_1 is included.)

Now, consider a case for which $|P(s)/Q(s)|s'=s_0=0$ and let $P(s_0)/Q(s_0)=k_0$; when point L approaches L_0, the point representing the value k_0, then equation 30 will have two close roots. Indeed, two different branches of a root locus must touch each other at that point and the locus will have a junction point. Similar statements are valid for multiple points of higher orders. Otherwise, in general as two points L_A and L_B move on two separate paths on the P-plane, the corresponding root-loci M_a and M_b do not cross each other.

Root Locus of a Real Rational Fraction for Real k

In servo problems, one is generally dealing with a rational fraction with real coefficients. Furthermore, generally point L moves along the real axis. For $k=0$, root points of equation 30 belong to $P(s)=0$ and for $k=\infty$, to the polynomial $Q(s)=0$. If it is assumed that none of the critical points of $P(s)/Q(s)$ (in recent mathematical literature roots of the derivatives of a function are called critical points) lie on the axis of the reals in P-plane, then the root locus has exactly p branches starting from roots of $P(s)=0$ and ending to roots of $Q(s)=0$, as we move from zero to infinity on the real axis of the P-plane.

Some of the properties of cyclides have already been established which obviously will be valid for this case also. Recently two elaborate doctoral theses related to this particular problem (root locus for real rational fraction when k is real) have been undertaken by Yeh[11] and Chu.[19] Reference 11 has particularly discussed this problem in detail and worked out loci corresponding to a simpler type of rational fractions.

Besides references 11 and 20, there are a number of articles concerned with the behavior of the root locus for real rational fractions. The existence of this literature relieves the writer of further emphasis on this particular problem. Nevertheless, it is noted that the latter literature in most cases is confined to the magnitude and angle criterion. Perhaps a more general approach based on conformal mapping properties along with a classical knowledge of potential curves would be more rewarding for those interested in research in the field of stability and system design.

Potential Curves

Consider a function $Z(s)$ of the complex variable $s=x+jy$, analytic but not identically constant in a region of the complex plane. In such a region, the following relations are self-evident

$$Z(x+jy)=U(x,y)+jV(x,y) \tag{38}$$

$$R^2=U^2+V^2 \tag{39}$$

$$\theta=\tan^{-1}\frac{V}{U} \tag{40}$$

The four functions defined in the foregoing satisfy the familiar Laplace differential equation

$$\Delta U=0 \tag{41}$$

$$\Delta V=0 \tag{42}$$

$$\Delta|\log R|=0 \tag{43}$$

$$\Delta\theta=0 \tag{44}$$

The curves $U(x,y)=\text{constant}$, $V(x,y)=\text{constant}$, form an orthogonal family in the rectangular system of co-ordinates. The same is true for the family $R=\text{constant}$, $\theta=\text{constant}$ in the polar system.

Now, to turn for a moment to the root-locus equation

$$U(x,y)+jV(x,y)=k \tag{45}$$

when, for instance, the point L moves on the real axis

$$V(x,y)=0 \tag{46}$$

and when point L moves on a circle with its center at origin

$$R(x,y)=\text{constant} \tag{47}$$

curves of equation 47 are obviously among the curves satisfying the Laplace equation. This remark suggests that for a deeper knowledge of the root-locus curves or the study of stability in engineering problems, one may profitably investigate the general properties of the curves satisfying the Laplace equation. It is the purpose of this section to give only an introduction to where and how one should start this investigation. The actual study of potential curves will not be undertaken here.

The study of the potential curves goes as far back as the first half of the 19th century, during the third quarter of which the study of level curves or isotherms became a part of mathematical physics. In addition to the previously mentioned references, the work of Klein, LaGoupilliere,[20] Guébhard,[21] and Holzmüller[22] should not be overlooked.

It should be noted that a serious study of the subject was not really undertaken before the turn of the century. It is mostly due to the work of Kasner that some further knowledge of potential curves has become available.[23]

A few typical properties of the potential curves which seem to have immediate bearing on related engineering problems will now be outlined.

PROPERTIES OF ROOT-LOCUS CURVES, CONSIDERED AS POTENTIAL CURVES

If $\phi(x\ y)=0$ is the equation of root locus in the rectangular system, then from the fundamental relation

$$\frac{\partial^2\phi}{\partial x^2}+\frac{\partial^2\phi}{\partial y^2}=0 \qquad (48)$$

the following properties might be concluded.

Theorem 4

If ϕ has a finite node, the branches cut at right angles.

Theorem 5

The p asymptotes of a potential curve of the pth order are real, concurrent, and disposed symmetrically about their common point, the angle between consecutive asymptotes being $2\pi/p$. (It may be of interest to note that this theorem already known to Briot, Bouquet,[24] and their students around 1875, has been recently independently rediscovered for its application to servo problems.[11])

Theorem 6

The point of concurrence of the asymptotes of ϕ is the center of gravity of unit masses placed at all the real centers of ϕ.

(For the definition of real center of a curve and the proof see reference 25.) These theorems are quite useful in the study of root-locus curves of some complexity.

It is hoped that the general methods outlined here may be of some use to those interested in basic research in the field of control. The unification of the two families of curves (potential and root-locus) will help in visualizing potential analogue fields, which are rather more familiar to engineers and physicists. In this respect the use of the potential analogue methods may be well worth further investigation. Guébhard in 1882[22] printed pictures of potential curves related to a number of fields of charges. If a short catalogue of similar nature may simplify the solution of many servo problems of wide interest, perhaps it is worth being considered.

A Line Voltage Regulator Having Magnetic-Amplifier Control

F. W. ANDERSON
ASSOCIATE MEMBER AIEE

Synopsis: Closely regulated supply voltages decrease maintenance, improve reliability, and simplify the design of electron tube and semiconductor circuits. There has existed a need for an alternating-voltage regulator which is effective for simultaneous variations in line voltage, load, and frequency, and which has a degree of reliability beyond that associated with electron-tube regulating circuits. Such a regulator, having a 3-kilovolt-ampere (kva) 115-volt 60-cycle rating is described. A power circuit consisting of a saturable reactor and a buck-boost transformer are controlled in a feedback loop by means of a cascaded 2-stage magnetic amplifier. Reference current is provided by a thermistor network and a silicon-carbide varistor is employed as a current preamplifier. These elements are insensitive to frequency over a ±5-per-cent range. The field of application for this type of regulator includes loads within the range of 1 to 20 kva where extremely fast regulation is not essential.

Paper 56-227, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 19, 1955; made available for printing December 20, 1955.

F. W. ANDERSON is with the General Electric Company, Schenectady, N. Y.

The mechanical design of the regulator and the design of the magnetic amplifiers and other coils were the responsibility of R. R. Gay and L. W. Stammerjohn respectively and their associates. C. B. Green and his associates designed the thermistor.

THE need for extremely reliable line voltage regulators capable of compensating for variations in input voltage and load, and which are unaffected by variations in frequency, is well recognized. Unfortunately all of the three major types of voltage regulators used for electronic loads have been compromise designs in the sense that they each have at least one undesirable characteristic. Ferroresonant regulators are sensitive to frequency and, if compensated, are suitable over only a limited load range. Electromechanical regulators are slow in response and are only as reliable as the electron tubes and electronic reference standard in the control circuit. Electronic regulators having a saturable reactor buck-boost power circuit have the same control-circuit disadvantages as the latter.

By replacing the control circuit in the latter type of regulator with a 2-stage magnetic amplifier having a semiconductor reference standard, it has been possible to overcome the aforementioned limitations. This paper describes such a regulator coded *TF161/U* and rated at 3 kva, 115 volts, and 60 cycles.

In addition to the requirement that the regulator regulate for severe variations in input voltage, load, and frequency, its weight was to be about half that of a similarly rated frequency-compensated ferroresonant-type regulator, and its reliability to be such as to preclude the use of renewable components such as electron tubes. Additional requirements included speed of response and output wave form as well as the usual military requirements for shipboard operation. Table I compares the characteristics of the *TF161/U* regulator with those of a 3-kva ferroresonant type employing a frequency-compensating network.

The requirement that regulation be

age, load, and frequency necessitated a feedback type of control. A survey indicated that an available buck-boost power circuit type of regulator, suitable in most respects, and having a feedback type of control, would serve as a good design point of departure. The significant weaknesses of the available design were its electron-tube control circuit which, because of tube failures, could result in high output voltage and in a short-lived unsaturated diode type of reference detector.

The buck-boost type of power circuit, because of its high efficiency, small size, weight, and reliability, is particularly attractive in the 1- to 10-kva range. An obvious solution then was to replace the control circuit with one having nonrenewable components and an improved long-life reference source. Fortunately the status of core materials selenium rectifiers, and circuitry was such that magnetic amplifiers proved a satisfactory substitute for tubes. A temperature-compensated thermistor similar to a type used successfully in other military applications fulfilled all requirements for a reference.

Power Circuit

The block diagram of the regulator, shown in Fig. 1, can be considered as consisting of two basic parts: a power circuit *T1* and *REG 3*, and a control circuit *AR1*, *TH2*, *CR9*, and associated components. The power circuit, which is not new in concept, consists of a buck-boost transformer and a saturable reactor, as shown in Fig. 2(A). By controlling the impedance of the saturable reactor by varying its d-c control current, the phase and magnitude of the buck-boost transformer current (winding *1–3*) can be adjusted to maintain a constant output

Vol. 7
Pt. 1
1956

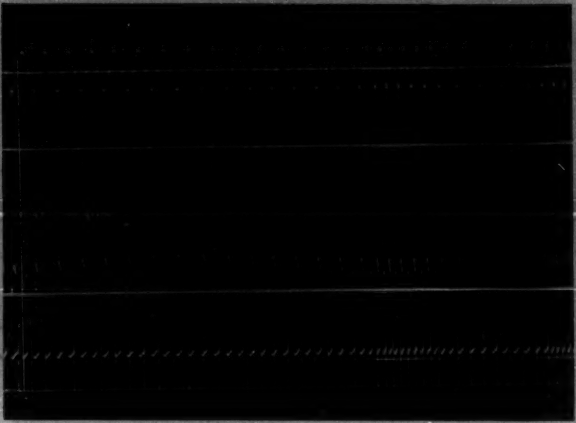

Fig. 6. Speed of response for a −10-ampere load change

voltage. This is accomplished by transformer action through the phasorial adjustment of the input voltage by winding *3–4* on *T1*. This type of power circuit control is phasorially indicated for low-normal-, and high-voltage inputs in Figs. 2(B), (C), and (D). Variations in load magnitude cause almost no change in the voltage relationships indicated because of the current-transformer action of transformer *T1*. As power factor of the load becomes increasingly lagging, the locus of the saturable reactor and buck-boost coil phasors are shifted as they would be for decreasing input voltage.

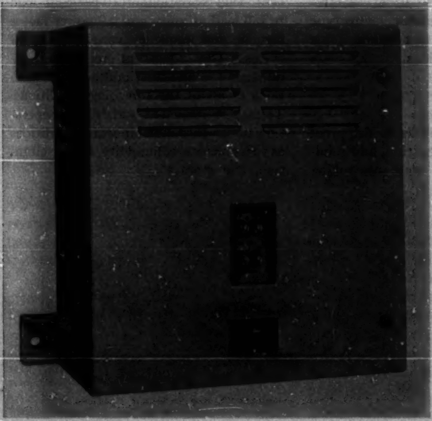
Control Circuit

The control circuit, shown in Fig. 3, consists of a 2-stage cascaded magnetic amplifier, a thermistor current standard *RT2*, a varistor detector circuit current amplifier *CR9*, and associated components. Both magnetic amplifiers are of the bridge self-saturating type with a-c windings in bridge legs common to an a-c input terminal. The two stages, which are mounted as a subassembly, are resistance-coupled. Control signals into the first stage are a rectified sample of the output voltage amplified by means of a silicon-carbide varistor *CR9*. By using a varistor with a voltage rating which is high as compared to the voltage applied to the control winding and the drop across the control resistor (volts-adjust), a current gain equal to approximately the exponent in the varistor current voltage equation $I=KE^N$ is realized. The exponent for the *CR9* varistor is about 4.

Thermistor *RT2* which supplies the the reference and bias current to the first stage magnetic amplifier has three ambient-temperature-compensating circuits associated with it. Two of these circuits are encased with the regulating network in the thermistor epoxide resin casting and the third is cast with the first-stage reference winding to compensate for variations in its resistance.

The output of the control circuit is coupled directly into the control winding of the power stage reactor. Despite the fact that the output of the second stage operates into a highly inductive load, the circuit is stable. This is probably so because of the high forward resistance of the selenium stacks used in the second magnetic-amplifier stage and because of the relatively low gain of the power reactor. It should be said that in both stages the selenium cells were operated at about 1/3 of their voltage rating to limit reverse current which has a degenerative effect and causes long-range instability.

After establishing the amount of loop gain required for the specified regulation, it was decided that two stages of amplification in the control circuit should be used rather than one. Two stages also provide the advantage over one stage of



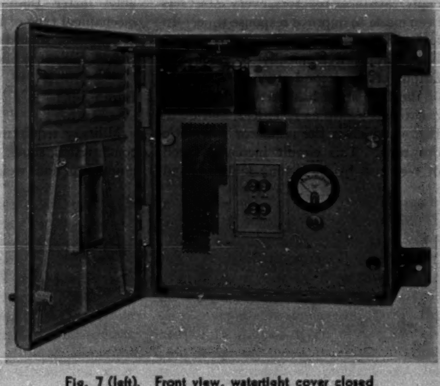


Fig. 7 (left). Front view, watertight cover closed

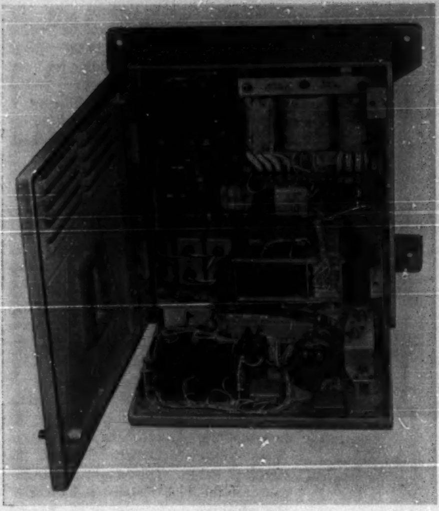
Fig. 8 (above). Watertight cover open



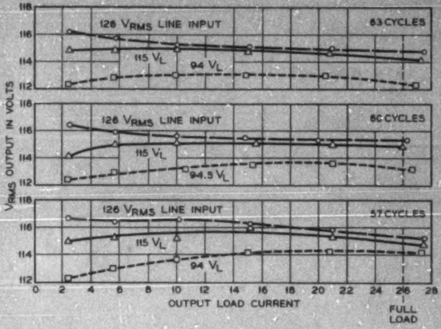


Fig. 9 (left). Watertight cover and hinged control panel open

Fig. 10 (above). Regulating characteristics

faster over-all response. Because only moderate gain per stage was required, magnetic-amplifier core materials, which are commercially more practical than high-nickel-content cores, were employed. The first-stage amplifier cores are grain-oriented silicon-steel tape-wound toroids cast in an epoxide resin casting. The second stage is tape-wound grain-oriented silicon-steel cut cores as are most of the other coils. All coils are insulted with class-*H* insulation.

Because of the inherent relatively slow response of magnetic amplifiers and especially saturable reactors, every effort has been made to improve response time. In addition to the 2-stage amplifier, a feedback circuit dynamically coupling the output of the second stage to the input of the first stage has been added. The network is shown as *R11*, *R12*, and *C6* in Fig. 4, which is the regulator schematic drawning. This circuit increases speed of response by increasing stability and preventing overshoot. To this extent it also serves as an antihunt circuit.

An oscillogram indicating speed of response for a −10-per-cent variation in input voltage is indicated in Fig. 5. The effect of a load variation of −10 amperes on output voltage is shown in Fig. 6. Response of the magnetic amplifiers, as evidenced by their output currents, are also indicated in these figures. These oscillograms establish the fact that for input voltage variations the response of the *TF161/U* regulator is not quite as fast as a ferroresonant type but considerably faster than the usual electromechanical type of regulator. This type of regulator should be fast enough for a wide variety of applications.

Equipment

Military requirements as to dripproof construction, shock, vibration, and minimum size and weight were controlling factors in equipment design. Fig. 7, which shows the cabinet with the cover closed, exhibits the inverted louvers which with holes in the bottom of the cabinet, provide chimney-effect convection cooling. Fig. 8 shows the voltage-adjust potentiometer output voltmeter and perforations in the front panel which assist in selenium stack cooling. In Fig. 9 the magnetic-amplifier subassembly is shown in the bottom right side of the cabinet. The thermistor is shown in the bottom left corner of the open panel. The regulator is suitable for bulkhead mounting and will operate unattended in ambient temperatures ranging from 0 to 50 degrees centigrade.

Performance

Fig. 10 indicates the fact that the regulator meets the over-all requirement of ±2-per-cent regulation for input voltage variations of +10 and −20 per cent, load variation of 10-per-cent load to full load at unity and 0.9 power factor lagging, and frequency variations of ±3 cycles. The 2-per-cent regulation requirement is met for simultaneous variations of all of the foregoing conditions. Tests also indicated satisfactory operation under extreme shipboard conditions as to temperature, humidity, shock, vibration, and storage.

A 72-Channel Radio System for Toll Telephone Service

M. C. HARP
NONMEMBER AIEE

M. H. KEBBY
NONMEMBER AIEE

Synopsis: A multichannel radio system is described which has been developed to meet the specific requirements of toll telephone service for transmitting medium channel loads over medium distances. Problems relating to reliability of service, noise, fading, cross-talk, interconnection and other requirements important to the telephone industry are discussed.

Application

THERE has been a growing demand in the past few years for medium-channel-capacity microwave equipment suitable for use in toll telephone service. Requirements for large-capacity long-haul service are well met by the existing *TD-2* equipment, which is widely used on the nationwide long-lines network. A number of small-capacity systems are available which, although finding considerable use in the industrial field, have only a limited application in the telephone industry. The system described here, designated as type *72B*, is intended to fill the gap between the existing large and small systems. It is tailored to the specific requirements of the telephone toll plant for the many medium-length routes where required channel capacity is measured in dozens rather than hundreds.

The requirements of radio equipment designed to be used for toll transmission in the telephone plant are largely determined by the requirements of the land lines with which the radio equipment must co-ordinate. These are: 1. reliability of the radio equipment should equal that of a wire line along a comparable route, 2. noise and crosstalk should meet standards established for toll circuits, 3. channels transmitted over the radio system must be integrated easily into the existing wire line plant, 4. engineering of a radio installation should be possible with no more effort than is normally required for a comparable wire line system, 5. the radio equipment should accept any of the commonly used wire line carrier systems with a minimum of special interconnecting equipment. These requirements may be summarized by stating that it is desirable to be able to treat the radio circuit as though it were just another wire line facility.

Radio's field of application has grown rapidly in the past few years, partly because of economic considerations which favor radio in many instances, and partly because the industry has come to know and appreciate the advantages of radio as a transmission medium. In many cases radio is providing lower cost connections: natural barriers such as mountains and water obstacles can frequently be spanned much more efficiently by radio circuits. In other situations radio is being used because of its greater reliability: a radio link is subject to less outage time and is easier to maintain than is a wire line through sleet or hurricane regions. Completely new circuit requirements to serve military installations or oil or mining developments are a natural application for radio.

In these situations right-of-way procurement and pole line installation costs are eliminated. In telephone plant, radio systems have even proved in on routes paralleling existing wire line leads where no particular problem existed beyond simply adding a new crossarm on existing poles. The centralized maintenance of a radio system is a very important advantage as compared with a submarine cable or a wire line constructed over rough or inaccessible terrain.

Frequency

For practical purposes, the frequencies available to the telephone common carrier services for multichannel toll transmission within the United States are limited to bands in the 900-, 2,500-, 4,000-, and 6,000-megacycle (mc) regions. Although higher frequencies have also been set aside for common carrier services, their use has been avoided because of the serious problem of precipitation attenuation over 6,000 mc. Large channel groups, which naturally require wide radio channels, at present utilize only the 4,000-mc band. Early use of the 6,000-mc band for large channel groups can be expected.

Type-*72B* equipment operates in the 900-mc band which provides adequate spectrum for medium channel loads. Choice of this frequency band was influenced by a number of factors including maintenance considerations, propagation characteristics, and equipment economies. These factors are of particular importance for the type of service contemplated for this equipment and may not be equally valid in selecting operating frequencies for systems of larger capacity. Equipment operating at 900 mc utilizes circuitry and techniques developed to such an extent for high-frequency and very-high-frequency service that the equipment can be operated and maintained by radio technicians without specialized training in the microwave art.

Fading at 900 mc is generally less severe than at the higher frequencies. As a rough approximation, it is believed that the necessary fade margin varies logarithmically with frequency. Generally, tests over any one given path at various frequencies show that the depth of fades seems to vary in decibels (db) at a rate of somewhat less than 10 log F_h/F_1; however, because the added susceptibility of the higher frequencies to fading caused by rain attenuation and effects resulting from the narrower beam width commonly used which result in increased sensitivity to duct propagation and fog bank refraction, it seems reasonable for practical purposes to figure that the necessary fade margin may vary in db as about 10 log F_h/F_1.

If proposed rule makings of the Federal Communications Commission are finally adopted, the band of frequencies from 890 to 936 mc will be assigned for use by the telephone common carrier service only. This band of frequencies can be divided readily into a total of 18 channels for *72B* equipment. This permits operation of three parallel duplex radio circuits in each of two directions from a central hub location, even where overshoot of signal to the station beyond the next repeater location is encountered. A maximum of 432 telephone channels transmitted over six duplex radio circuits can be terminated in one location. In Fig. 1 is shown a frequency allocation for three parallel duplex circuits which is used for a system extending from Eugene, Oreg., over mountainous terrain to several coastal locations. Even more channels can be terminated at a single location where the overshoot problem can be avoided by judicious location of repeater sites.

Paper 56-16, recommended by the AIEE Radio Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted July 19, 1954; made available for printing October 31, 1955.

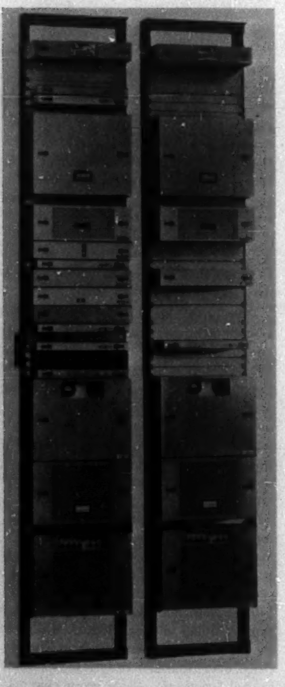

Fig. 2. Two typical duplex equipment assemblies. Radio transmitter, receiver, and associated equipment mounted on each rack. Assembly on left includes auxiliary equipment for supervision and control

Radio Equipment

Two rack bays of type-*72B* equipment are illustrated in Fig. 2. Each rack is equipped with transmitter, receiver, and a-c power supplies, and one rack includes auxiliary equipment for supervision and control. The radio equipment is rack-mounted and equipped with dust covers in the same manner as for widely used types of telephone carrier systems to conform with standard toll office layouts. Every effort has been made in equipment arrangements to provide systems which can be operated and maintained by personnel with a minimum of training and experience in radio techniques.

Block diagrams of the radio transmitter and receiver are shown in Fig. 3. The modulator, converter and power output panels for the transmitter, and the demodulator and converter panels for the receiver have been developed for the type of wide-band low-distortion operation required of multichannel systems used for toll telephone service.

The Serrasoid modulator used in the transmitter allows a high signal-to-noise ratio with extremely low distortion characteristics. It provides a crystal-controlled frequency source and has no circuitry requiring critical adjustment. The modulator provides a phase-modulated signal which is converted to frequency modulation through a 6-db-per-octave corrector (slope) network. Phase modulation is accomplished by clipping a saw-tooth wave form at various points along its slope, the point of clipping being dependent upon the instantaneous amplitude of the modulating signal. Since the slope of the saw-tooth wave form may be made exceptionally linear, amplitude distortion is virtually negligible.

Low-frequency signals from the Serrasoid modulator are translated to a higher frequency, amplified, and multiplied to the final frequency in the 900-mc band. Rated peak frequency deviation is 500 kc. Ordinary negative grid-type tubes are used throughout the equipment, and a *2C39A* triode (lighthouse tube) is used in the power output stage. This tube, rated for up to 100-watt dissipation, is operated at about a 20-watt input to yield an output of from 5 to 8 watts. Users are consistently obtaining useful tube life in excess of 5,000 hours when

Fig. 3. Block diagram, type-72B transmitter and receiver

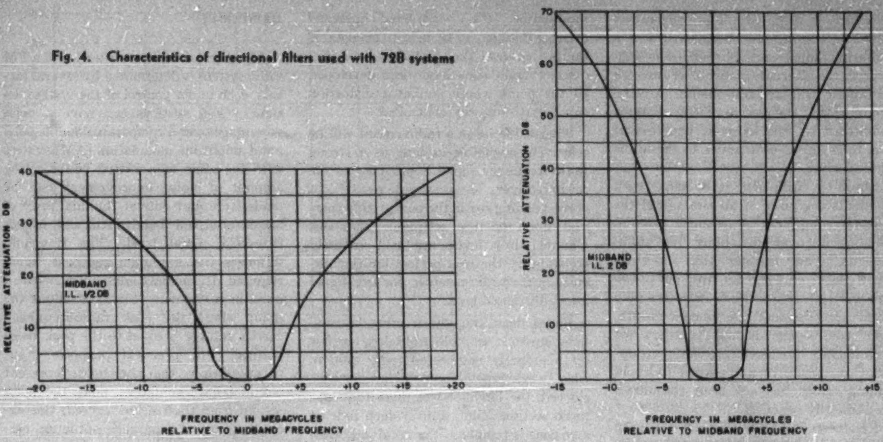

Fig. 4. Characteristics of directional filters used with 72B systems

operating in this conservative manner.

A straightforward double superheterodyne receiver circuit is used with a silicon crystal as the first mixer. Receiver band width is approximately 2 mc to accommodate more than 99.9 per cent (%) of the total side-band power for the rated peak deviation of 500 kc, and about 99% of the side-band power for a deviation of 800 kc. This is equivalent to less than 30-kc bandwidth per channel for a full 72-channel system, a comparatively good usage factor for a 900-mc microwave system. The receiver includes a Codan or squelch circuit which mutes the receiver noise output in the absence of a received signal in much the same manner as is common in the mobile radio services.

Ten-foot mesh parabolic reflectors are most commonly used with *72B* systems although smaller sizes can be employed under favorable operating conditions where less antenna gain is required. A directional filter arrangement included with equipment assemblies permits the use of a single antenna for both transmitting and receiving. With these filters the cross coupling from transmitter to receiver is controlled to lower limits than would be the case if two separate antennas were used without filters. Various directional filter arrangements are used to permit the use of one antenna for up to three receivers, up to three transmitters, or two receivers and two transmitters. The filters consist of 1/4-wave coaxial cavities connected in cascade to provide the necessary suppression to adjacent radio channels. Characteristics of typical transmitting and receiving directional filters are shown in Fig. 4.

Repeaters

Two general types of repeaters have been commonly used in microwave systems.

One type, known as a back-to-back repeater, simply connects the output of a receiver to the input of a transmitter.

The second type, known as an intermediate-frequency or heterodyne repeater, converts the received signals to an intermediate frequency band for amplification. The amplified signals are then converted to a new transmitting frequency.

Although a heterodyne repeater does not introduce the nonlinear distortion associated with modulation and demodulation, it has the serious disadvantage for telephone applications of providing no ready access for dropping or inserting channels at repeater points. Since the need for channel dropping and insertion is quite frequent in short to medium haul toll circuits, the *72B* system has been designed to use back-to-back repeater arrangements. Through conservatively engineered circuits and such techniques as the Serrasoid modulator, the amount of distortion associated with modulation and demodulation has been reduced to a point where about ten repeater sections may be connected in tandem before distortion noise contributions of the radio equipment become the limiting factor in system engineering. Since many more than ten sections are readily practical when compandors are used with the carrier equipment, *72B* systems can be extended well beyond 500 miles if desired.

Supervision and Stand-by Arrangements

Associated with type-*72B* radio equipment is a supervisory, control, and alarm system designated type *51B*. This system utilizes coded tone transmission between a control center and a number of remote stations to actuate a wide variety of alarm, supervisory, and control equipment. Because each radio installation presents different control problems, the *51B* system has been designed on a flexible basis to permit a variety of arrangements. Information concerning the activation of a supervised alarm or transfer function at a remote point will be transmitted automatically to the control center. With stand-by and transfer equipment provided, a failure is immediately corrected and the alternate equipment transmits full information as to what the automatic equipment has done. In the event of a total failure of a radio section, major alarm is given, but the information as to which end of the section is dead can be sent to only one end of the system by the supervisory system. Personnel at the control center can verify the status of all remotely supervised functions immediately by observing a lamp field display. Remote control of the distant equipment is provided from the control points by dialing a coded signal. The *51B* system can supervise up to 80 remote functions and can control up to 90 remote activities divided among up to eight remote locations.

A complete duplicate radio system is provided as stand-by equipment for any location where an unusually high degree of reliability is required. The transmitted power is continuously monitored and a radiation failure causes automatic switchover to the alternate transmitter through automatic transfer equipment. A tone originating at the preceding transmitter is monitored by the receiver, and loss of this tone causes switchover to the alternate receiver.

Stand-by equipment is operated with filaments energized at all times, and the transfer equipment is arranged to complete switchover in about 150 milliseconds. This transfer time is sufficiently fast to prevent the drop-out of toll circuit connections. Since transfers may occur as infrequently as once a month, even considering manual transfers for maintenance purposes, providing equipment to transfer rapidly enough to avoid dialing errors has not been considered economically practical.

Reliability in wire line service is usually assured by providing alternate wire pairs and alternate routes. It is therefore not usually necessary to back up wire line installations with full stand-by alternate equipment. Similarly, when a radio system is part of such a network, stand-by provisions would not ordinarily be required. In cases where no alternate route to the radio system is available, absolute continuity of service may be required. With stand-by equipment and automatic transfer, the radio system is highly reliable with circuit continuity limited only by the probability of fading. This fading can be controlled by careful and conservative engineering of the system.

Noise

Noise in radio links is of two distinct types, each originating from a different source, and each must be handled as a separate problem. One type, resulting from the thermal noise at the receiver input, is heard by the listener as a constant hiss. The second type, caused by nonlinear distortion in the radio equipment, is called "babble" and is similar in many respects to unintelligible crosstalk in a wire line system. The characteristic hiss or rushing sound of thermal noise is less disturbing than distortion noise. Since babble results from distortion products falling into other than the disturbing channel, it creates a noise problem which does not exist in a single-channel radio system.

A frequency-modulated system such as the *72B* provides a means of reducing the thermal noise by choosing a deviation ratio which yields some nominal frequency modulation (FM) wide-band improvement. Babble can be held to acceptable limits because the techniques of frequency modulation have been developed to the point where nonlinear distortion can be satisfactorily controlled.

Thermal noise in a radio circuit will be relatively negligible as long as a strong radio frequency signal is provided to the radio receiver. A signal fade results in a corresponding rise in the background thermal noise on the telephone channels. Channel drop levels are held virtually constant by the near-perfect limiting circuits in the radio receiver, for any signal above threshold level.

Fades deep enough to bring thermal noise up to noticeable audibility are few on a properly engineered radio system. Also, when repeatered systems are considered, the likelihood of more than one radio section falling into a deep fade at any time is remote. The total fade time should be expected to amount to only minutes per month, and on this basis the noise for maximum fade is permitted to rise to a high value. In contrast, distortion-caused noise is contributed simultaneously by all repeater sections and is fairly continuous during busy periods. A much lower level of distortion noise must therefore be maintained.

Signal-to-noise ratios as poor as about 30 db are acceptable as the bottom limit for a deep fade. (The signal-to-noise ratio quoted compares a zero-volume-unit talker in a channel to a 3,000-cycle noise bandwidth in the channel.) This corresponds to per-channel noise of about 52 db adjusted (dba) at zero level. Such noise value is acceptable with the limitation that is should not be attained more than about 0.01% of the time, or about 4 minutes per month. This noise limit is set at about the point where dialing circuits may be affected by noise hits, or where supervision may be interrupted long enough to cause a disconnect. Thermal noise during normal propagation periods is negligible for all practical purposes.

Exact predictions of fades to be expected for a given repeater section are difficult to make. However, it has proved practical to approximate the outside limit of the fade and engineer the system to these requirements. For type-*72B* equipment, fades up to about 44 db can be tolerated over a typical span of about 40 miles without exceeding the specified maximum noise. This large margin is achieved with a moderate transmitter power of about 5 watts and with relatively high antenna gains of about 27 db each.

Bandwidth

The thermal noise contribution of a FM radio system is determined by several factors, each under control of the system designer. FM systems can have a noise advantage over a comparable double side-band amplitude modulation (AM) system with the same transmitted power. The amount of noise improvement can be made large, but only at the dual price of larger occupied bandwidth and higher threshold signal level. The threshold signal is the minimum received signal required to achieve detection with a noise improvement; occurs at about the point where the peak radio-frequency carrier voltage is equal to the peak noise voltage. For practical purposes input signals below the threshold represent circuit failure conditons, since the noise output from the receiver exceeds the signal output. To provide optimum performance at the bottom of a fade, an FM radio system should be designed so the threshold is just beyond the point where noise reaches the target of 52 dba at zero level, as discussed. This provides maximum FM noise improvement with the greatest possible fade margin. In *72B* equipment a receiver bandwidth of about two mc coupled with a receiver noise figure of about 14 db provides an effective compromise between noise improvement and threshold signal level.

Emphasis

In a pure FM system, noise amplitude at the output of the receiver decreases from the high end of the baseband toward the low end at a rate of 6 db per octave. To compensate for this inherent characteristic, equipment usually includes an emphasis system to equalize the noise across the baseband. A pre-emphasis network in the transmitter shapes the baseband so that modulation from the low-frequency channels is decreased at about the same rate as the noise decreases. A curve showing the deviation as a function of frequency is shown in Fig. 5. In other words, more of the total frequency deviation is caused by the high-frequency channels than by those of low frequency. A complementary de-emphasis network at the receiver restores the baseband frequencies to a flat spectrum.

Loading

When used with usual single-side-band frequency-division multiplex equipment, the load fed to the radio transmitter consists predominantly of a group of speech

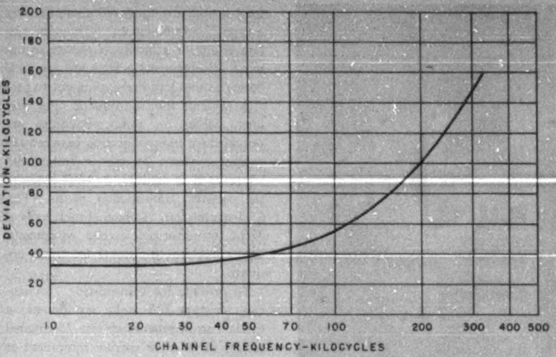

Fig. 5. Deviation of zero dbm tone at zero level as a function of frequency

side-bands. The complex wave form of this modulating signal has a relatively high peak to average ratio, but the highest peaks occur only occasionally during the busiest hours. Detailed study of the statistical properties of a group of single-side-band speech channels has been made by Holbrook and Dixon[1]. In telephone terms, this source indicates that when 72 channels are put through a common transmitting device such as an amplifier, FM transmitter, or receiver, etc., and when the output level is zero db, then the output or load capacity of the device on peak signals should be approximately 18 db above 0.001 watt [18 db above 1 milliwatt (dbm)]. Zero-db level is the reference level at the 2-wire input to toll circuits (toll testboard level). A device at zero-db level output operates with zero-db gain between its output and the toll circuit input. The loading of the system must be set so that these occasional peaks do not cause excessive frequency deviation resulting in objectionable intermodulation noise or babble. Unless excessive deviation is held to short periods, the noise limits will be exceeded. On the other hand, if the system is adjusted for less than the maximum possible deviation, part of the fade margin is sacrificed.

The emphasis treatment used in the *72B* system changes the system loading considerations by modifying the signal peaks of the 72-channel group. Analysis shows that this modification results in a reduction of the peak load factor by about 3 db. Therefore, emphasis permits a net loading of the system of about 3 db higher than would be possible without emphasis. With this information, it has been found that if the highest frequency channel (at 300 kc) causes a deviation of ±150 kc (with a zero dbm signal), the peaks will exceed a deviation of ±800 kc for about 1% of the time during the busy hour. Since each peak lasts for only 1 or 2 milliseconds, distortion resulting from the peaks will not be apparent to the listener, even though the total overload time approaches 36 seconds in 1 hour.

It may be noted that the rated maximum deviation of the *72B* system is ±500 kc, although a deviation of ±800 kc is reached on 1% busy hour peaks. The ±500-kc deviation figure is one which has been used in equipment design including tuned circuit bandwidth requirements in order to achieve acceptable performance most of the time. In contrast to the distortion created in negative feedback amplifier circuits commonly used in carrier equipment, which increases rapidly beyond the overload point, the distortion created in the *72B* system rises gradually under overloaded conditions and does not suddenly increase as in the case of the negative feedback amplifier. For this reason, considerable overdeviation for short-time intervals may be accepted by the *72B* system.

FM Improvement Factor

The per-channel thermal noise improvement of a multichannel FM system in which the noise spectrum has been corrected by emphasis has been shown to be related directly to the square of the per-channel deviation ratio; see the Appendix. This improvement refers to the difference in noise in a channel transmitted over an FM system as compared with a standard reference of a single-channel double-side-band AM system with the same carrier power and with 100% modulation.

In the *72B* system, a zero dbm test tone at zero transmission level placed in the top channel (300 kc) causes a frequency deviation of ±150 kc. This is a deviation ratio of one-half for the system's worst channel. The improvement is therefore $(1/2)^2 = 1/4$, or −6 db as compared with the 100% modulated AM double-side-band system. For purposes of this comparison it is assumed that a zero dbm tone (at zero level) produces 100 per cent modulation of the AM transmitter. Since it has been shown that a test tone of +18 dbm (at zero level) presents loading equivalent to that of 72 channels, it follows that the per-channel level of the 72-channel AM system must be reduced to −18 dbm to present an equivalent load of 0 dbm. This results directly in an 18-db degradation of per-channel signal-to-noise ratio. Since the *72B* system improvement factor (per channel) is −6 db referred to a 100% modulated AM system and the 72-channel AM system must have a per-channel modulation factor 18 db below 100%, it follows that the *72B* effective noise improvement per channel is 12 db above that of a comparable double side-band AM system of the same carrier power.

Distortion

On toll telephone circuits the level of noise caused by nonlinear distortion is expected to be held to very low levels. Such circuits are repeatedly degraded by the tandem connection of many repeater sections to form links and by the ultimate tandem connection of several links to complete a toll circuit. For this reason, one of the targets in the design of a radio system is that a single radio repeater section should contribute only about 1% or 2% of the total noise objective for the end-to-end toll circuit. To meet this objective the channel signal-to-noise ratio in a single radio section should be above 60 db; i.e., the average noise should not exceed 22 dba (*F1A* weighting at zero level) during the busy hour. This requirement can be restated in terms commonly used by radio engineers to state that any product from a zero dbm tone at zero level, or cross product of two such tones, should not exceed about 0.1% distortion for a system such as the *72B*. Experience indicates that radio equipment adjusted to the use of this procedure will yield satisfactory operating results.

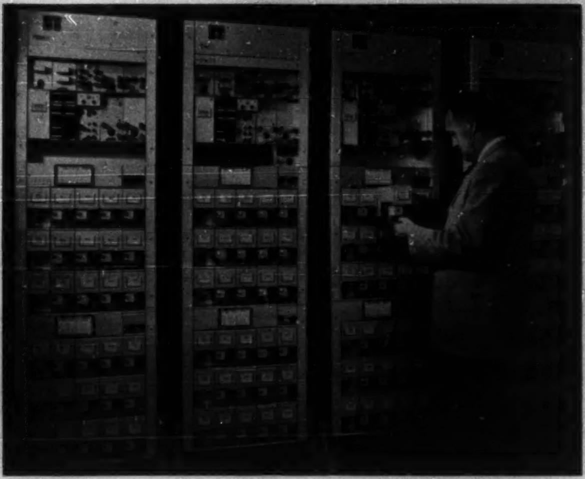

Fig. 6. Two 48-channel terminals, type-45BX carrier telephone equipment

Typical Link

A typical line of sight section for a *72B* system might be as long as 40 miles. At this distance the space loss between antennas should be approximately 127 db. With total antenna gains of about 54 db and about a 4-db attenuation in transmission lines, the net loss between transmitter and receiver would be about 77 db. With a transmitter output of +37 dbm (5 watts), the received signal level would be −40 dbm (2,200 microvolts in 50 ohms). Since the receiver FM improvement threshold is at about −84 dbm, at which point noise in the worst channel is 52 dba, about 44 db remains as the absolute maximum fade depth which can be tolerated. This amounts to a fade margin of over 1-decibel per mile, a value considered adequate for all but the most adverse locations. In an area where fading is expected to be especially severe, the length of the radio span should be reduced to about 25 to 30 miles in order to provide a fade margin of $1^1/_2$ db or more per mile.

Carrier-Channelizing Equipment

Almost any of the commonly used wire line carrier systems can be used for channelizing type-*72B* radio equipment. Although not usually used for groups of fewer than 12 channels, the system has found some application for extending 12-channel cable carrier systems across water barriers.

A recently developed carrier system, the *45BX*, has been specifically adapted for transmitting up to 48 channels over a type-*72B* radio circuit. This new system is one of a family of carrier equipment arrangements which use identical basic channel terminal equipment to provide systems for transmission over wire lines, cables, or radio. Facilities are provided for interconnecting between the various systems at carrier frequencies wherever it is desirable to shift between the various transmission media. Fig. 6 illustrates four 24-channel rack bays of *45BX* miniaturized carrier equipment. Two complete 48-channel terminals are shown.

To provide for transmitting 72 channels on type-*72B* radio equipment, a special arrangement of six 12-channel groups of *45*-class carrier equipment is being developed, utilizing frequencies from 12 to 300 kc.

Installations

About 25,000 channel miles of *72B* equipment will have been installed to provide toll telephone service by the end of 1954. The equipment is being used to meet a variety of problems. In one case a radio link has provided circuits between Seattle, Wash., and Victoria, B. C., to replace previous facilities which included a circuitous land line and a failing submarine cable. Other installations are being made in locations throughout the mountainous terrain of the Pacific coastal area, where wire line failures have been commonplace during severe winter weather. Plans are also being made to replace existing wire line sections in other regions where land line reliability has been a problem in the past. Several installations are under way to provide communication service to new military bases remote from existing wire line facilities. A number of systems are being used in the Hawaiian Islands where submarine cables have not been practical for inter-island circuits.

Perhaps the most significant of the type-*72B* installations are those being made where no particular barriers exist,

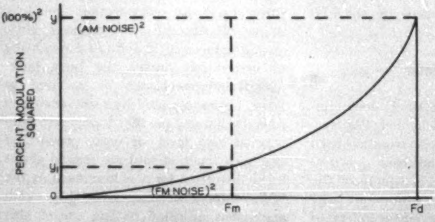

Fig. 7. Wide-band FM systems. F_m = highest modulated frequency. F_d = deviation of highest modulated frequency. D = deviation ratio

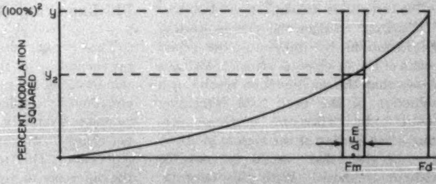

Fig. 8. Channelized FM systems

or where the capacity of existing land lines could be increased with additional crossarms. Several such installations have been or are being made, in some cases because radio systems can be installed more rapidly than a pole line, but usually because economic studies have shown that the additional channels will cost less, will be easier to maintain, and more reliable if radio is used. There can be no doubt that the next few years will witness a marked swing to the use of radio in the normal growth of short and medium haul toll circuits in the telephone industry.

Appendix

The following shows the development of a simple method for obtaining the signal-to-noise ratio and the FM-AM improvement factors for both wide-band and channelized FM systems. Fig. 7 shows the noise spectrum for both FM and AM systems. The AM noise is proportional to the noise contained below the dashed rectangle whose area may be designated

$$(N_{AM})^2 = yF_m \tag{1}$$

The FM noise is proportional to the area under the parabolic curve up to y_1 and may be designated

$$(N_{FM})^2 = \frac{y_1F_m}{3} \tag{2}$$

Also

$$y = kF_d^2 \tag{3}$$

$$y_1 = kF_m^2 \tag{4}$$

$$\frac{y}{y_1} = \frac{kF_d^2}{kF_M^2} \tag{5}$$

By definition

$$D = \frac{F_d}{F_m} \tag{6}$$

Substituting equation 6 in equation 5

$$\frac{y}{y_1} = D^2 \text{ or } y_1 = \frac{y}{D^2} \tag{7}$$

Substituting equation 7 in equation 2

$$(N_{FM})^2 = \frac{F_My}{3D^2} \tag{8}$$

Dividing equation 8 by equation 1 gives the ratio of FM to AM noise squared

$$\left(\frac{N_{FM}}{N_{AM}}\right)^2 = \frac{F_My}{3D^2F_My} = \frac{1}{3D^2} \tag{9}$$

The improvement factor for wideband FM systems is thus equal to

$$\text{improvement factor}_{WB} = 10 \log 3D^2 \tag{10}$$

For channelized FM systems see Fig. 8.

Assume a narrow channel centered at frequency, F_m. The AM noise may be designated by

$$(N_{AM})^2 = y\Delta F_m \tag{11}$$

and FM noise by

$$(N_{FM})^2 = y_2\Delta F_m \tag{12}$$

Dividing equation 12 by equation 11 gives

$$\left(\frac{N_{FM}}{N_{AM}}\right)^2 = \frac{y_2\Delta F_m}{y\Delta F_m} = \frac{y_2}{y} \tag{13}$$

Since

$$y = kF_d^2$$

and

$$y_2 = kF_m^2$$

$$\frac{y_2}{y} = \frac{F_m^2}{F_d^2} = \frac{1}{D^2} \tag{14}$$

Therefore the ratio of FM to AM noise is given by

$$\left(\frac{N_{FM}}{N_{AM}}\right)^2 = \frac{F_m^2}{F_d^2} = \frac{1}{D^2} \tag{15}$$

The improvement factor for channelized FM systems is thus equal to

$$\text{improvement factor}_{\text{chan}} = 10 \log D^2 \tag{16}$$

The per-channel noise of an FM system may be obtained simply by calculating the AM noise and applying the improvement factor obtained in the foregoing for any given channel. The emphasis characteristic if used need not be considered, providing the actual deviation of the desired channel is known.

Discussion

R. S. Caruthers, (Lenkurt Electric Company, Inc., San Carlos, Calif.): Since 1954, when the paper was originally presented, the *72B* radio system has been modified to broaden its range of application to the telephone industry. The modified version has been designated as type *72C*. This discussion compares the *72B* with the *72C* and notes the possible applications of the latter.

The *72B* radio system was designed to provide 72 toll-quality telephone channels for medium-length routes where neither the small-capacity nor the large-capacity systems such as *TD-2* were applicable. The *72C* radio system with 120-channel capacity was the next logical step toward filling the gap between small- and large-system capacity.

In addition to nearly doubling the channel capacity, the *72C* system includes an optional directional-filter arrangement designed to permit three transmitters and three receivers to be operated over the same antenna. Thus, using the frequency assignment shown in Fig. 1, up to 360 voice channels can be transmitted over any multisection system using only two antennas for each section. When 240 or fewer voice channels are required, three radio channels can be installed with one channel acting as stand-by for either of the other two. For a single-section system, two antennas can be used at each terminal and a total of 720 voice channels transmitted over six parallel radio channels using the same route. All six radio channels can be transmitted in the 890 to 940-mc fixed service band.

The industrial band from 952 to 960-mc is wide enough to accommodate one radio channel carrying 120 voice channels.

The increased channel capacity of the *72C* radio system dovetails with the development of new models of type-*45BX* carrier channelizing equipment. This equipment provides up to 120 voice channels in a base band frequency range which is directly applicable to *72C*, from 12 to 528 kc. In addition, the *72C* base band has been extended to 552 kc in order to accommodate a Bell System supergroup (60 channels using frequencies from 312 to 552 kc). This permits the *72C* system to be used with Western Electric type-*L* carrier or with European-manufactured radio carrier systems that also utilize this frequency allocation.

Several minor changes were included in the modification of the *72B* to increase the reliability and improve performance. One of the most important changes was that of improved limiter circuits, which permits achievement of the full FM improvement for signal levels down to threshold. A reduction in the receiver noise figure exceeding 2 db has been achieved, with the use of recent low-noise mixer diodes, together with improved matching and better intermediate-frequency amplifier performance. A modification to the modulator has reduced the basic modulator noise appreciably. Changes have been made in components and in the ventilation, which have improved reliability at high temperature.

Cyclic Decimal Codes for Analogue to Digital Converters

JOSEPH A. O'BRIEN
NONMEMBER AIEE

CYCLIC decimal codes may be used in analogue to digital converters of the reading type. Decimal number output is easily obtained for display to human operators or processing by decimal calculators.[1,2,3] Decimal numbers, of course, are more generally used than binary and more frequently in simple computations.

For definiteness, this paper is limited to a discussion of an encoder in which each measurable angular position of an input shaft is represented by a unique combination of conducting and nonconducting segments. These segments may be on a flat disk having many concentric tracks, as in Fig. 1, or segments may be on a cylinder having many adjacent tracks about the same axis, as in Fig. 2. All conducting segments are connected to a common voltage source. The remarks of this paper are equally applicable, however, to other analogue to digital converters which assign to a physical position a unique code group which may be easily converted to a decimal number form.

A brush in contact with a particular track may be either conducting or nonconducting at a particular time depending on whether it is on a conducting or nonconducting portion of its track. The brushes are then used as 2-state or binary elements. N independent binary elements can assume 2^N different combinations of states. Since $2^3=8$ and $2^4=16$, at least 4 independent binary elements must be used to represent the 10 decimal digits 0 to 9.

Four tracks and their associated brushes are used to assume, in sequence, 10 different combinations of binary states. A particular combination of states is consistently used to represent a particular decimal digit in equipment associated with the encoder. Since the 10 digits could be arbitrarily represented by any 10 and the 16 possible combinations of states of 4 binary elements, $16!/6!$ or more than 29 billion binary decimal codes are possible.[4]

The present discussion is a systematic investigation of codes which will optimize the following parameters:

Readout error.
Number of encoder brushes.
Average brush current.
Number of translator components.

Cyclic Number Sequence and Cyclic Digit Code

Fig. 3 shows an array of conventional decimal numbers with a line passing through successive numbers. When the line moves from left to right, successive numbers differ in only one digit. When the line moves from right to left to connect successive numbers, these numbers differ in more than 1 digit. Fig. 4 shows a cyclic number sequence. The line connecting successive numbers moves from left to right or right to left making a change of only one digit between successive numbers. A cyclic number sequence is defined as a sequence of numbers in which pairs of successive numbers differ in only one digit. The digits which differ are successive digits such as 0 and 1, 1 and 2, 8 and 9, or 9 and 0.

Readout error and the number of brushes may be minimized by using a cyclic number sequence and a cyclic digit code. If a conducting brush is represented by 1 and a nonconducting brush is represented by 0, the states of four brushes at a particular time may be represented by a 4-digit binary number which in turn represents a decimal digit. A cyclic decimal code is defined as a set of 10 words, each containing four binary digits, in which successive words including the first word and the last word differ in only one binary digit.

An angular position encoder which uses both a cyclic number sequence and a cyclic digit code, will have only one brush change from conducting to nonconducting or the reverse in going from one sector to the next. In one complete revolution of the input shaft all consecutive pairs of words read from the brushes differ in only one binary digit. In this respect the code is similar to the reflected binary code and only one set of brushes lying on a radial line is required.

Encoders using a conventional number sequence require at least two brushes per track to prevent errors in readout that might occur at shaft positions where the output number changes in many digits at one time. Brushes, in general, will not lie on radial lines.

Map Method of Code Analysis

The 16 combinations of states of four binary elements may be represented by the map shown in Fig. 5.[5,6] The four successive values of both the horizontal and vertical co-ordinates are 00, 01, 11, and 10. If the vertical co-ordinate is termed *ab*, and the horizontal co-ordinate is termed *cd*, the co-ordinates of a square *abcd*, are a 4-binary digit number. Each square on the map represents a unique 4-digit binary number or word. The decimal number within the square is equal to the binary number expressed by the co-ordinates of that square.

Squares that are geometrically adjacent differ in only one binary digit. Two squares at opposite edges of the map, in the same horizontal row or in the same vertical column, differ in only one binary digit. Squares located symmetrically about a horizontal (or vertical) centerline also differ in only one binary digit. These conditions are defined as "adjacent." Designing a cyclic decimal code is then a simple geometry problem. A progressive sequence of 10 squares must be chosen so that successive squares, including the 10th square and the first square are adjacent.

Two pairs of consecutive digits, 4 and 5, and 9 and 10, are also 9's complement pairs. Each of these four digits must be adjacent on the map to its 9's complement. If the six additional digits are also chosen so that any digit and its complement differ in one particular binary digit, 9's complementing is easily mechanized. The complementing of 9's is required to convert from cyclic to conventional

number sequence. Code analysis is simplified if a digit and its 9's complement occupy squares on the map symmetrical about a horizontal centerline. (Identical results would be obtained from symmetry about a vertical centerline.)

Initial investigation proceeds using half-maps of eight squares, five of which are occupied by digits. Fig. 6 shows the half-maps in which five squares may be connected by a line lying entirely within the map. This classification is rather arbitrary, but gives an illustrative example from the set of 48 maps that must be investigated. Five squares may be chosen from a group of eight squares in ${}_5C_8=8!/5!3!=56$ ways. Of these, ${}_4C_7=7!/4!3!=35$ selections contain the word "0000." Twenty-one selections (${}_5C_7=7!/5!2!$) do not contain the word "0000." Of the 35 selections, 30 meet the requirement of a cyclic decimal code which produces 9's complement by complementing one particular binary digit. Of the 21 selections, 18 form cyclic decimal codes.

Permutation of a code corresponds to relabelling the brushes in a different order or shifting the relative positions of four tracks radially without changing the identifications of the brushes. Complementation of a code corresponds to interchanging conducting and nonconducting segments in a particular track. Complementation of any of the 48 codes produces another code which is a member of the set of 48. Analysis of 48 half-maps then, is a rigorous investigation of all desirable possibilities.

A systematic way of specifying a particular half-map would list the three empty squares with the use of the decimal digits found in the squares of Fig. 5. Thus the map listed in Fig. 6 as class 1 might be called code 567.

Fig. 7 shows a decimal symmetry map, i.e., the number within a square is the sum of the number of 1's in the coordinates of that square. Since a 1 corresponds to a conducting brush, this map is very useful in choosing codes that have words containing the smallest number of 1's.[7] In choosing a binary decimal code to use minimum brush current, it would be desirable to use the following conditions: one word containing four zeros, four words each containing one 1, and five words each containing two 1's. That is, no more than two brushes are ever conducting at the same time. This would give a sum of 14 conducting brushes for the 10 decimal digits. Unfortunately, this code is not cyclic. Fig. 8 shows the code in each class containing the smallest sum of 1's of the coordinates of the occupied squares. Classes 1, 2*a*, and 2*c* (codes 567, 347, and 357) are the only codes having sums of 15. Classes 2*b* and 2*d* (codes 347 and 167) have sums of 17, as do seven additional maps not shown.

Since cyclic codes cannot be easily mechanized for addition or other arithmetic operations, it is desirable to translate to a constant positive weight code. A cyclic decimal code is desirable that can be translated to the 1, 2, 4, 8 code with the minimum number of components. The map of the translator output code is shown in Fig. 9; Capital letters *A*, *B*, *C*, and *D* are used to represent the output lines. If translator input lines are labeled with lower case letters *a*, *b*, *c*, and *d*, the

$C = c'd$

$D = a(b'c' + d') + a'd(b + c)$

$S = 19$

squares in which digits of a cyclic code should be chosen are indicated in the remaining maps.

Figs. 10 and 11 show maps of the optimum codes for coded disk elements and coded drum elements respectively. Since a minimum brush current code will not also result in minimum number of translator relay springs and the reverse, the "optimum" codes are the best compromise between these two conflicting requirements.

Here, a disk code is defined as a code that does not use the word "0000," and a drum code does use the word "0000" Fig. 12(*A*) and (*B*) show the patterns these codes will form on the coded elements. In Fig. 12(B) a permutation of the code in Fig. 11 is used to obtain the most desirable placement of tracks.

An A-C Kelvin Bridge for the Audio-Frequency Range

BERNADINE L. DUNFEE
ASSOCIATE MEMBER AIEE

THE present trend in electrical measurements indicates the need for a test method by which the ratio and phase angle of current transformers can be measured at adiuo frequencies with the same accuracy as they are now measured at power frequencies. The theoretical aspects of several test methods are being investigated at the National Bureau of Standards. It is essential to this study to determine the extent to which the present test equipment,[1] comprising 4-terminal impedors and a mutual inductor in a potentiometer network, can be utilized in high-frequency measurements. As part of this program, an a-c Kelvin bridge has been developed for measuring the characteristics of the 4-terminal impedors at audio frequencies. At present the bridge method permits resistance and phase-angle measurements up to 6,000 cycles per second (cps). A substitution technique is employed in which the bridge is balanced first with the unknown and then with a primary standard having a computable skin effect and phase angle. The resistance of the computable standard is previously adjusted and accurately measured in terms of a d-c standard resistor. The range of adjustment for the standard extends from 0.1 to 0.05 ohm. With additional computable standards now under study, and minor modifications of the circuit, measurements can probably be extended to a minimum resistance of 0.001 ohm and a maximum frequency of 10^4 cps.

The Computable A-C Standard

A reference standard of a-c resistance must be designed so that its inductance and ratio of a-c to d-c resistance (characterized by the term skin effect) may be computed. A coaxial arrangement with the potential leads attached to either the inner or outer tube is one of the few configurations for which these quantities can be evaluated. The computable standard to be described is of the coaxial type; the arrangement of its potential leads provides a minimum phase angle and maximum protection from coupling between its potential circuit and other current-carrying parts of the network.

CONSTRUCTION

A cross-sectional view of the standard appears in Fig. 1(A). The outer seamless copper tube A has a nominal outside diameter of $1^1/_8$ inches and a wall thickness of 0.065 inch. The inner seamless resistance tube C is arranged coaxially with the outer tube and both are brazed at one end to a connecting ring B. An extension of this ring is necked down to accommodate a coaxial connector. The current terminals, located at the end opposite the brazed joint, are $2^1/_2$-inch square copper blocks having a thickness of 1/4 inch. The ends of the coaxial tubes are centered in these blocks and are brazed to them around their entire circumference. A system of cuts through the blocks, Fig. 1(B), in the form of a symmetrical labyrinth provides four equally spaced entries for the current and assures a more nearly uniform current distribution at the ends of the tubes.

The inner tube, serving as the resistance element, is a nickel-chromium-iron alloy. The outside diameter is 5/8 inch and the wall thickness is 0.01 inch. It has a resistivity of the order of 92 microhm-centimeters (cm) (about 50 times that of copper) and a temperature coefficient of approximately 125 parts per million per degree centigrade. (This relatively high temperature coefficient would be undesirable in most applications. However, with the measuring technique employed here, the resistance of the shunt for a given setting is measured on direct current just prior to its use in the a-c bridge so that the resistance remains constant so long as the current is adjusted to the same value.) For a given configuration, the combination of a thin wall and high resistivity reduces both the phase angle and the skin effect. The over-all length of the standard is about 144 cm with an active length of 133 cm for a 0.1-ohm setting.

A brass rod W, 0.125 inch in diameter and 250 cm long, is located along the axis. At the end where the tubes are brazed together the end extends through an insulating bushing into the constricted portion of B. The end of the rod as well as the cylindrical section of B form the potential terminals P_1 and P_2 and the potential leads are brought away as a coaxial pair with the use of modified *AN* fittings. At the other end, where the current terminals are located, the brass rod emerges from the impedor and extends into the control mechanism along its axis. The control mechanism moves along the rod into cylinder C and, by means of an expandable spider, forms the potential connection p.

The control assembly formed from three coaxial tubes and equipped with suitable adjustments is rigidly attached at one extremity to a vertical arm which rests on a track extending out 110 cm from the impedor. When a clamp that locks the vertical arm to the track is released, the unit can be moved into the resistance tube. The track and the platform on which the impedor is mounted are formed from a single length of brass rigidly fastened to a wood base. The supports for the impedor and the control mechanism are brass, insulated from the metal base, and arranged so that the entire assembly is aligned.

The procedure by which the potential connection p is effected is illustrated in Fig. 2. The inner tube I has an externally threaded section near its end and terminates in a slotted knife-edge taper. The middle tube M carries a fixture threaded both internally and externally and terminates in a double conical wedge K. The outer tube O has an internally threaded section and terminates in a slotted knife-edge taper. Control knob F can be rotated to operate the double wedge. Movement of the wedge into the mating cone expands the fingers of the outer knife edge forcing them to grip the inner wall of the resistance tube. Turning control knob E moves the inner tube I into the wedge causing its fingers to grip the brass rod and completes the operation. A differential screw S coupled to the outer tube O provides a fine adjustment.

SKIN EFFECT

The resistance of the a-c standard must be measured eventually on direct current. It is necessary, therefore, to design the shunt so that its skin effect is either negligible or computable. The skin effect of conductors and shunts has been treated by a number of writers.[2] The effect in

Paper 56-25, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 17, 1955; made available for printing November 10, 1955.

BERNADINE L. DUNFEE is with the National Bureau of Standards, Washington, D. C.

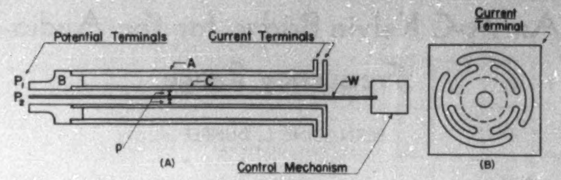

Fig. 1(A). Cross section of the computable standard. (B). Current terminal block

tubular-type shunts, completely defined by the four parameters, namely, resistivity ρ, permeability μ, wall thickness d, and frequency f can be computed from an equation developed by Silsbee.[2] At the operating frequencies of the computable standard, the a-c resistance is given closely enough by the equation

$$R_{ac}=R_{dc}\left(1-\frac{7m^4d^4}{360}\right)$$

where $m^2=8\pi^2 f/\rho$. The permeability is assumed equal to unity. The ratio of its a-c to d-c resistance at 10^4 cps is $(1-4\times 10^{-7})$.

Phase Angle from Geometrical Considerations

Silsbee has made an extensive analysis of this problem for several configurations.[2,4] In his treatment of coaxial assemblies, expressions for the regional flux linkages are obtained from the circuital form of Ampere's law. The inductance for a given configuration is given by the ratio of the active flux linkages Φ to the current I where Φ is the sum of only those linkages instrumental in producing an electromotive force (emf) across the potential terminals. The corresponding phase angle is for an impedor used in a potentiometer network where, at balance, there is no current in the detector circuit and, therefore, none in the potential leads of the shunt.

The expression that defines the inductance is altered when the impedor becomes an element of the Kelvin bridge network. The small currents in the potential leads of the impedor become sources of magnetic flux and introduce additional self- and mutual-inductance terms. To interpret correctly the influence of these lead currents as dictated by the bridge balance equation, it was necessary to extend Silsbee's analysis and to obtain the expression for the inductance, taking into account the altered current distribution. Computed in this manner, the algebraic sum of the active flux linkages per unit length in a standard of the given configuration is given by

$$\Phi=\Phi_{CIC}-\Phi_{CIW}-\Phi_{EWW}-\Phi_{WWW}$$

Referring to the view of Fig. 3(A) as seen from a cut across the diameter, these flux linkages are identified as follows:

Φ_{CIC} = the average flux linkages in region C arising from the total current I entering the shunt. This current, Fig. 3(B), includes the current in the rod W designated as δi, and that in the resistance tube designated as $I-\delta i$

Φ_{CIW} = the flux in region C, produced by the current I ($I-\delta i$ plus δi), linking the rod W

Φ_{EWW} = the flux in region E, produced by the current δi in the rod, linking the rod W

Φ_{WWW} = the average flux linkages in region W produced by the current δi in the rod

The linkages expressed in terms of the currents and the dimensions of the inner tube and rod are (see the Appendix for a typical derivation)

$$\Phi_{CIC}=\left(t+\frac{t^2}{6}-\frac{t^4}{30}\cdots\right)\delta i+\left(\frac{2}{3}t-\frac{t^3}{15}-\frac{t^4}{20}\cdots\right)(I-\delta i)$$

$$\Phi_{CIW}=\left(2t+t^2+\frac{2}{3}t^3\cdots\right)\delta i+\left(t+\frac{t^2}{6}-\frac{t^4}{30}\cdots\right)(I-\delta i)$$

$$\Phi_{EWW}=\left(2v+v^2+\frac{2}{3}v^3\cdots\right)\delta i$$

$$\Phi_{WWW}=\frac{1}{2}\delta i$$

where

$t=(a_2-a_1)/a_2$
$v=(a_1-r)/a_1$
a_2 and a_1 = the outside and inside radii of the resistance tube C
r = radius of the rod W

By definition the series expansion terms express the respective inductances in the centimeter-gram-second system of units. It will be noted that Φ_{CIC} as well as Φ_{CIW} has two components: flux linkages associated with a self-inductance L and those associated with a mutual inductance M. These can be written, therefore, in the forms

$$\Phi_{CIC}=M_{CW}(\delta i)+L_C(I-\delta i)$$

$$\Phi_{CIW}=L_W(\delta i)+M_{WC}(I-\delta i)$$

The flux linkages $\Phi_{EWW}=L_W'\delta i$ and $\Phi_{WWW}=L_W''\delta i$ are associated with self-inductances. The question arises regarding the significance of these components and their proper selection in computing the phase angle of the standard. The self-inductances L_W, L_W', and L_W'' of the rod are lead inductances which, like the lead resistance of the d-c network, need be considered only in the examination of the auxiliary lead balances. It can be shown that the phase angle of the standard must include only the components L_C and M_{WC} if the phase angle of the unknown is to be valid for a potentiometer network when computed from the bridge equation. The remaining quantity M_{CW} may be considered as an extraneous mutual inductance since its presence gives rise to an induced emf that is registered in the bridge circuit. Its effect, if appreciable, enters the balance equation as a correction term. The phase angle of the standard was computed as 3.1 minutes at 10^4 cps and the effect from the extraneous mutual coupling was found to be negligible.

The A-C Kelvin Bridge[5,6]

The D-C to A-C Transformation

Referring to Fig. 4, the balance equation for the d-c network is[7]

$$\frac{A}{B}=\frac{E}{F}\left(\frac{1+\alpha/E}{1+\eta/F}\right)+\frac{L(D+\gamma)}{B[(C+\beta)+L+(D+\gamma)]}\left(\frac{E+\alpha}{F+\eta}-\frac{C+\beta}{D+\gamma}\right)\tag{1}$$

The two auxiliary balance equations are

$$\frac{A}{B}=\frac{\alpha}{\eta}+\frac{L(D+\gamma)}{B[(C+\beta)+L+(D+\gamma)]}\left(\frac{\alpha}{\eta}-\frac{C+\beta}{D+\gamma}\right)\tag{2}$$

$$\frac{A}{B}=\frac{E+\alpha}{F+\eta}+\frac{D+\gamma}{B}\left(\frac{E+\alpha}{F+\eta}-\frac{C+\beta}{D+\gamma}\right)\tag{3}$$

where equation 1 is the balance equation for the main bridge shown in Fig. 4, equation 2 is the balance equation for the auxiliary bridge formed by short-circuiting units E and F with a link L' of negligible resistance, and equation 3 is the balance equation for the auxiliary bridge formed when links L and L' are both removed. The balances indicated

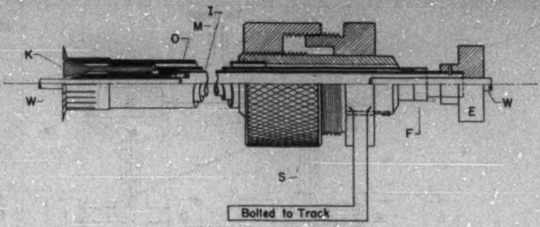

Fig. 2. Control mechanism

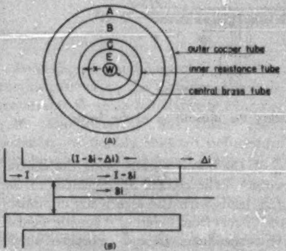

Fig. 3(A). Regions used in flux linkage calculations. (B). Current distribution

by equations 2 and 3 permit adjustment of the lead resistances α, β, γ, and η, including the resistances of the potential leads l_1, l_2, l_3, and l_4, into unique ratios such that equation 1 can be reduced to the simple form

$$\frac{A}{B}=\frac{E}{F}$$

With resistances replaced by impedances, the balance equations for the a-c network are similar in form to those for d-c operation. It is to be noted, however, that the link resistance L which appears in the numerators of equations 1 and 2 becomes an impedance of the form $Z_L' = Z_L + j\omega(M_1 - M_2)$ in the a-c case and includes, in addition to the impedance Z_L, associated with the link, the inductive reactance associated with these emfs of mutual inductance developed in the potential leads of A and B common to loop III. If the emf of mutual inductance developed in the 4-terminal resistors A and B by the currents in their potential leads (l_1, l_2, l_3, and l_4) are neglected, the phase angle as well as the resistance of resistor A, or B, given by these equations is the one to be measured, i.e., the phase angle of the resistor in a potentiometer network. (However, the inductive reactance terms associated with the emf of mutual inductance developed in the potential leads by currents in the current circuits of the shunts are included in the appropriate impedance term of equations 1, 2, or 3.)

Inclusion of these emf of mutual inductance, however, alters the equation; typically $Z_A/Z_B = \zeta\,(1+a+jb)$ where ζ represents the right-hand side of equation 1, 2, or 3 in its a-c form. Whether or not the correction $(a+jb)$ is negligible depends on the magnitudes of the bridge elements and on the mutual inductances present in the 4-terminal shunts. In the substitution method, only the mutual inductance of the standard and of the unknown is significant since shunt B is common. As previously mentioned, the extraneous mutual inductance is computable for the standard; it is not computable for the unknown so that, to some extent, the correction term is indeterminate. However, when the resistances of the bridge elements are large, the correction term is sufficiently small so that, with some knowledge of the construction of the unknown, its mutual inductance can be estimated with sufficient accuracy. For example, in the measurements of the 4-terminal shunts used in current-transformer testing, the errors introduced by neglecting the term $(a+jb)$, for an assumed mutual inductance of 0.4 microhenry, are less than 3 parts per million for the resistance and 0.1 minute for the phase angle at a frequency of 10^4 cps.

Lead Balances

In the d-c bridge the influence from lead and contact resistances is minimized through auxiliary balances that force these resistances into appropriate ratios. In the a-c bridge, lead inductances as well as resistances must be considered. Assuming that the lead resistances are adjusted to their proper ratios, an analysis shows that the necessity for lead inductance balances can be avoided by making the leads short, operating with elements of large impedance and utilizing the substitution technique. For example, with 1,000 ohms in each of the bridge ratio arms and with an uncompensated lead inductance of 1 microhenry, the resulting error in phase angle would be less than 0.2 minute at 10^4 cps. A switching arrangement provides for a quick transfer of the network from a d-c to an a-c source. Thus, with the network energized on direct current, the necessary lead resistance balances are made. The network is then transferred without change to an a-c source and the main bridge is balanced, no lead inductance balances being required.

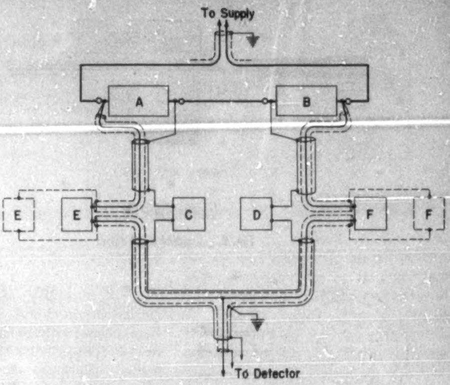

Fig. 7. Circuit indicating the disposition of the leads

Bridge Components and the Defining Equation

Capacitors rather than inductors were chosen as the reactive bridge balance elements to avoid the spurious flux linkages that characterize an inductive network. The bridge circuit without its shielding network is shown in Fig. 5. The computable standard (or the unknown resistor) occupies the *A* arm. *B* is a 4-terminal resistor the phase angle of which is more inductive than either the standard or the unknown; *D* and *F* are 1,000-ohm audio-frequency resistance cards. The resistors of arms *C* and *E* are audio-frequency decade resistance boxes, with settings greater than 500 ohms in all cases; the capacitors are continuously adjustable from 100 to 1,100 microfarads. The defining equations for the a-c resistance and the phase angle, when the substitution method is employed, are

$$R_X=\frac{R_E R_S}{R_E'}[1+\omega R_E C_E(\omega R_E' C_E'-\omega R_E C_E)] \tag{4}$$

$$\theta_X \approx (\omega R_E' C_E'-\omega R_E C_E)+\theta_S \tag{5}$$

where

R_E and R_E' = the resistance settings, at balance, of the *E* arm when the unknown and the standard respectively occupy the *A* arm

C_E and C_E' = the respective capacitance settings

R_S and θ_S = the resistance and phase angle of the computable standard

The Shielding Network

The effects of stray capacitances must always be considered in an a-c network but the task of either eliminating or reducing them to negligible amounts becomes more difficult the higher the frequency and the more stringent the accuracy requirements. In the Kelvin bridge, a stray capacitance across either the *E* or *F* element produces a maximum error; the error becomes several orders of magnitude smaller if produced by an equal capacitance across the *A*, *B*, *C*, or *D* elements. A study of this problem as well as pertinent experimental measurements indicated that an adjustable Wagner network would provide the most effective shielding, particularly if its leads α' and η', Fig. 6, were arranged to protect the corresponding leads α and η of the measuring circuit.

The diagrams of Figs. 6 and 7 show the bridge circuit (supply and detector circuits are omitted) and illustrate the disposition of the leads. The α' and η' leads of the Wagner arms are flexible braided shields that protect the critical α and η leads. The β and γ leads of the inner bridge arms form a sheath around the respective coaxial pairs α, α' and η, η', the α and η leads being the central wires. (The coaxial arrangement of the β, γ leads with the α, η leads minimizes the effects from external magnetic fields.) Thus the inner wire and its braided shield together with the outside flexible sheath form a triple coaxial configuration. Special adjustable resistors for balancing the lead resistances were incorporated in the triple coaxial arrangement. Further precautions were taken by connecting to ground each enclosure in which the elements were housed, the physical ground being located at the junction of the Wagner arms. With the capacitances between the elements thus fixed their effects were eliminated by the substitution method.

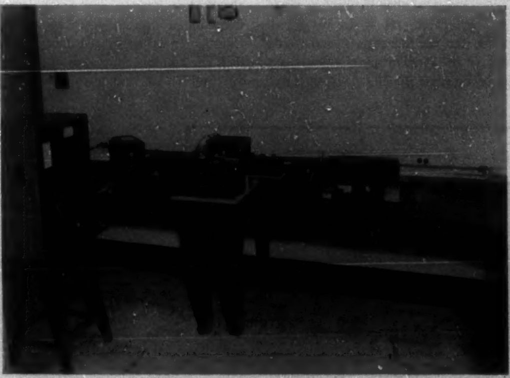

Fig. 8. Kelvin bridge

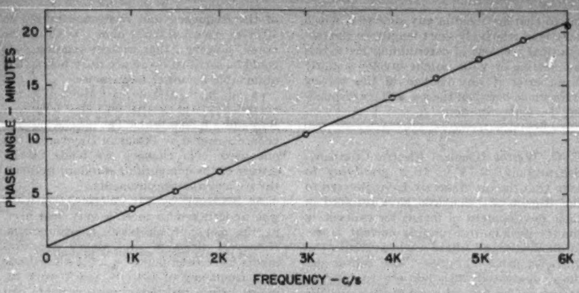

Fig. 9. Plot of experimental data obtained for a 0.1-ohm shunt

To realize the high accuracy desired in the measurement, the detector circuit is required to sense an unbalance of 1 microvolt. The detector has three components: a doubly shielded impedance matching transformer having a 1 to 4 ratio; a preamplifier with a gain of about 30; and a wave analyzer that serves both as a sharply tuned filter and as an indicator of unbalance. The shields of the three units together with their common lead are connected to ground.

Precautions were taken to protect the circuit against external magnetic fields as well as minimize the magnetic coupling between the bridge members. The coaxial arrangement of the inner and outer arms afforded some protection. Loop areas were further reduced by arranging the units in two tiers so that the circuit could, in effect, fold back on itself. The bridge compactness is shown in Fig. 8.

Results

The results obtained in a series of measurements on a 0.1-ohm shunt indicate the usefulness of the test method. The measurements include a-c determinations over a frequency range of 1,000 to 6,000 cps taken on several days over a span of 4 months. Minor modifications, rearrangement of the bridge and supply circuits, and substitution of the bridge elements were made between tests. The modifications added to the convenience of operation but neither they nor the other changes produced appreciable differences in the results. All values of resistance obtained at a given frequency were in substantial agreement and their average was within 20 parts per million of the value measured in the d-c bridge normally used in certification work. No significant skin effect was evident over this frequency range. At any given frequency the values of phase angle agreed to within 0.5 minute. The averages plotted against frequency are indicated in Fig. 9. It will be noted that the experimental values fall on a straight line passing through the origin, justifying the approximations made in deriving equation 5. Furthermore, an extrapolated 60-cycle value is within 0.1 minute of the value obtained by another method in 1931 when the shunt was constructed.

Summary

An adjustable 4-terminal resistor, having a computable phase angle, is described and its a-c performance is analyzed. A shielded a-c Kelvin bridge network suitable for measuring the resistances and phase angles of 4-terminal resistors in the audio-frequency range has been described. Both a-c and d-c sources are available and the network is easily transferred from one to the other. The resistance of the adjustable standard is set to the nominal value of the unknown and measured on direct current in terms of a standard d-c resistor. The bridge is then balanced on alternating current first with the standard and then with the unknown in the network, with lead resistance balances made on direct current prior to the a-c measurements. The validity of the test method is demonstrated by a typical example.

Appendix. Derivation of the Flux Linkages Φ_{CIC}

Let the current in the wire W be δi and that in the cylinder C, $(I-\delta i)$, both having a direction into the paper. Assume the permeability equal to unity and let the inner and outer radii of C be a_1 and a_2. The flux density B at a distance x from the common center is by Ampere's law $\int Bdl = 4\pi I_n$ where I_n is the current enclosed by a circular path of length l having a radius x. Since the current δi in the wire is completely enclosed, and the fraction $(x^2-a_1^2)/(a_2^2-a_1^2)$ of the current in the cylinder $(I-\delta i)$ is enclosed, the foregoing equation when integrated is

$$B=\frac{2}{x}\delta i+\frac{2}{x}\left(\frac{x^2-a_1^2}{a_2^2-a_1^2}\right)(I-\delta i)$$

The flux linkages averaged across region C may be written

$$\Phi_{CIC}=\frac{1}{\pi(a_2^2-a_1^2)}\int_{a_1}^{a_2}2\pi x dx\int_x^{a_2}Bdx$$

$$=\frac{1}{\pi(a_2^2-a_1^2)}\int_{a_1}^{a_2}2\pi x dx\int_x^{a_2}\left[\frac{2}{x}\delta i+\frac{2}{x}\left(\frac{x^2-a_1^2}{a_2^2-a_1^2}\right)(I-\delta i)\right]dx$$

This yields

$$\Phi_{CIC}=\left(-\frac{2a_1^2}{a_2^2-a_1^2}\ln\frac{a_2}{a_1}+1\right)\delta i+\left(\frac{a_2^2-3a_1^2}{2(a_2^2-a_1^2)}+\frac{2a_1^4}{(a_2^2-a_1^2)^2}\ln\frac{a_2}{a_1}\right)(I-\delta i)$$

Define $t=(a_2-a_1)/a_2$. After expanding the logarithmic terms and substituting the value of t as indicated, the equation reduces to

$$\Phi_{CIC}=\left(t+\frac{t^2}{6}-\frac{t^4}{30}\cdots\right)\delta i+\left(\frac{2}{3}t-\frac{t^2}{15}-\frac{t^4}{20}\cdots\right)(I-\delta i)$$

Discussion

H. N. Hayward (University of Illinois, Urbana, Ill.): This paper is of particular interest because of the application made of a Kelvin bridge to measure the a-c resistance of low-valued resistors. It also points out some of the problems that arise in attempting to extend the methods of making accurate measurements from the power frequencies into the audio-frequency range.

The measurements reported were based on the use of a computable a-c standard of resistance having one potential terminal that could be adjusted in position to vary the amount of resistance between the potential terminals. Although not stated in the paper, it is assumed that the procedure used was to set this computable and adjustable standard to the value required in making the a-c measurement and then, without changing the setting of this computable standard, to determine the resistance value of the standard in a d-c bridge. It seems advisable to emphasize this procedure, which would be necessary because of the relatively large error that might result if any setting of the adjustable computable standard should be changed between an a-c measurement and the corresponding d-c determination. This problem is similar to that involved in any slidewire, which here is of relatively short length, so the mechanical problem of determining the actual a-c setting or value might involve a fairly large error if any change in the setting were made between the a-c and corresponding d-c determinations.

C. O. Werres (General Electric Company, Schenectady, N. Y.): It is gratifying to note that the questions we have directed to the Bureau of Standards have resulted in their development of means for calibrating shunts used in determining current transformer ratio and phase angle at audio frequencies above 60 cycles. The author and those associated with her are to be congratulated for this advance of the art. We look forward to the contemplated extension of the frequency and resistance ranges to 10,000 cycles and 0.001 ohm. It should be noted, however, that present requirements could be satisfied by an accuracy below that obtainable at power frequencies.

Bernadine L. Dunfee: The measuring procedure assumed by Professor Hayward is the one used. No changes are made in the setting of the computable standard between the a-c and d-c measurements.

As indicated by Mr. Werres, this work was undertaken to meet a very real need in the field of electrical measurements. However, although preliminary measurements have been made on a 0.1-ohm shunt at a frequency of 10^4 cps, much work remains before resistance measurements can be extended to 0.001 ohm at this frequency.

A First Look at Random Noise

S. O. RICE
NONMEMBER AIEE

Synopsis: The aim of this paper is to discuss some elementary properties of a type of noise which has been called "Gaussian" or "random." The power spectrum is discussed and its relation to the autocorrelation function is pointed out. Two probability distributions associated with the noise are described.

OCCASIONALLY one encounters engineering problems which involve the random fluctuations of an electric current or voltage, or some other quantity. These fluctuations are often called "noise." A considerable amount of information about such fluctuations has been obtained by mathematicians who have studied the subject under the name of "stochastic processes." The aim of this paper is to present an introduction to the subject by mentioning some of the main properties of the fluctuations, which in accordance with engineering usage, will be spoken of as noise.

There is a wide variety of noises, but this paper will be restricted to those called "stationary processes." That is, they go on about the same forever, and their statistical properties do not change with time. Furthermore, the discussion will be concerned mostly with a special kind of noise which has been called "random" or "Gaussian" noise. Its second name comes from the fact that its statistical properties are closely related to the Gaussian distribution used in probability theory. Random noise is a mathematical idealization of certain types of noise occurring in nature. One such type is thermal noise, which occurs as a result of the thermal agitation of electrons in a conductor.

Noise consisting of impulses that can be heard separately is not considered to be random noise in the sense that the term will be used here. For example, noise from relay clicks and ignition noise from automobile engines are not random noises. When such trains of impulses are expressed as Fourier series or as Fourier integrals, there is a considerable amount of correlation between the phases of the various components. This is not true for random noise.

Why are engineers interested in the properties of noise? One reason is that noise produces interference in transmission systems. A knowledge of the statistics of the noise is helpful in estimating the quality of a proposed system while it is still in the design stage. In some cases the noise is large in comparison with the signal, as in the problem of detecting airplanes or submarines. The question here is how best to overcome the noise. Again, carrier communication systems are coming into use which employ a wide band of frequencies to transmit a large number of telephone channels. The output of such a system resembles random noise, and this fact may be used in designing the system.

Random noise has been studied more extensively than other types of noise. The probable reason for this is that it is easier to handle mathematically than the other types. Furthermore, some frequently encountered noises, such as thermal noise in conductors and shot-noise in vacuum tubes, are close approximations to random noise.

An oscillogram of a random noise current might look somewhat like that shown in Fig. 1. Here $I(t)$ is plotted vertically and the time t goes on horizontally. Throughout this discussion, $I(t)$ will stand for a random noise current. The division of the time scale into strips of length T will be needed later in connection with representations for the noise.

What are the various statistical properties of this curve, i.e., such things as the mean square value of $I(t)$, the percentage of time $I(t)$ exceeds some given value I, or the expected number of zeros per second? Some of these may be readily obtained by working directly with the oscillogram. For example, the expected number of zeros per second may be obtained by a count of the number of times the curve crosses the axis during a long interval of time. Other properties may require some calculation; an example is the mean square value of $I(t)$. However, in most problems an oscillogram is not provided. Generally, all that is known about the noise is its power spectrum, about which more will be said later. It may be shown that the statistics of $I(t)$ are completely determined by the power spectrum.

Paper 56-73, recommended by the AIEE Communication Theory Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 20, 1955; made available for printing January 12, 1956.

(A)

(B)

Fig. 2. Narrow-band power spectrum and corresponding random noise current

Representation of Random Noise

One method often used in the study of random noise is first to represent $I(t)$ by some kind of mathematical expression. There are several representations in use. They take the form of functions of time which contain a number (generally infinite) of random variables as parameters. The random parameters are needed to get the randomness into the noise.

One of the oldest and most frequently used representations is the Fourier series[1]

$$I(t)=\sum_{n=1}^{\infty}\left(a_n\cos\frac{2\pi nt}{T}+b_n\sin\frac{2\pi nt}{T}\right) \qquad (1)$$

where T is a very long interval of time, as indicated in Fig. 1, and the a_n's and b_n's are independent random variables. The representation is so named because it is suggested by cutting the oscillogram of Fig. 1 into strips of length T and expanding $I(t)$ on each strip as a Fourier series. When this is done it is found that the numerical values of the coefficients for any one strip are so irregular that they show no relation to each other (aside from being of the same order of magnitude) or to the corresponding coefficients for the other strips. This is in accordance with the assumption that the a_n's and b_n's are independent random variables. The standard deviations of the a_n's and b_n's are fixed by the power spectrum of $I(t)$.

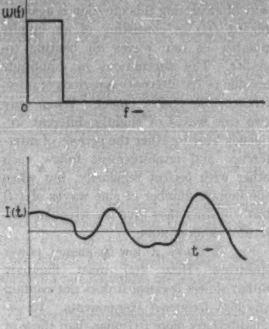

Fig. 3. Low-frequency power spectrum

Representations may be used directly in practical investigations. For example, suppose a random noise voltage is applied to a filter network. What are the statistical properties of the output current? A Fourier series representation for the applied voltage may be written down and the response to each sinusoidal component computed from network theory. The output current is then given by the sum of these response. The result is a Fourier series representation for the current from which the desired statistical properties may be computed.

Again, suppose that a random noise current passes through a hot-wire ammeter. If the noise is fluctuating slowly enough the needle of the ammeter will also fluctuate a little. The rate and the amount of fluctuation will depend upon both the time constant of the meter and the properties of the noise. For example, how can the rms value of the needle fluctuations be calculated? This may be done by starting with the expression

$$D(t_0)=\int_{-\infty}^{t_0} e^{-\alpha(t_0-t)}I^2(t)\,dt$$

It may be shown that the needle deflection at the instant t_0 is approximately proportional to $D(t_0)$. In this integral α depends upon the time constant of the ammeter. When $I(t)$ is replaced by its Fourier series representation, equation 1, and the integration carried out an expression is obtained for $D(t_0)$. The rms value of the needle fluctuations may be obtained by working with this expression.

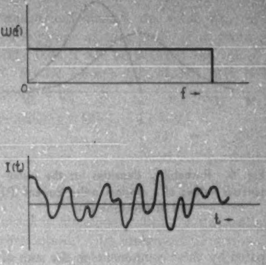

Fig. 4. Wide-band power spectrum

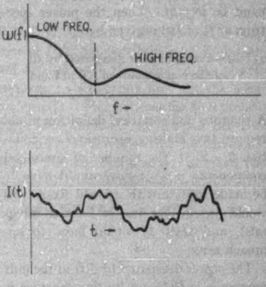

Fig. 5. General power spectrum

The Power Spectrum

As its name indicates, the power spectrum measures the distribution of the power in a noise over the frequency range from zero to infinity. Many kinds of noise besides random noise have power spectra. However, for the sake of simplicity, only the random noise current $I(t)$ will be considered.

Suppose $I(t)$ to be composed of a great many sinusoidal components as indicated by the Fourier series representation, equation 1. Suppose further that $I(t)$ flows through a resistance of 1 ohm. Each component will dissipate its share of power, and the total power dissipated is the sum of the powers dissipated by the components.

Choose some narrow frequency band, say the band between f and $f+\Delta f$. A certain number of components will lie in this band, and the total power dissi-

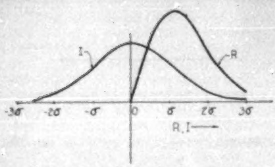

Fig. 6. Probability densities for the instantaneous values of a random noise current I(t) and its envelope R(t)

pated by these components is the sum of the powers of the individual components. Let the average of the total power in the band be $w(f)\Delta f$. Then the power spectrum $w(f)$ of $I(t)$ is given by

$$w(f)\Delta f = \text{average power dissipated by all of the components of } I(t) \text{ in band } (f, f+\Delta f) \quad (2)$$

A rigorous mathematical definition would require two limiting operations on equation 2. First, the number of sinusoidal components in $(f, f+\Delta f)$ would have to be made infinite with Δf held fixed (this would require the use of Fourier integrals), and then Δf would have to approach zero.

The power dissipated by $I(t)$ in the unit resistance is $I^2(t)$ and its time average is $\overline{I^2(t)}$. This average power is also equal to the sum of the average powers of all of the components. The sum is obtained by integrating the power spectrum over the entire frequency range. Thus,

$$\overline{I^2(t)} = \int_0^\infty w(f)df$$

When the power spectrum of $I(t)$ is known, something may be said about the general appearance of $I(t)$ as a function of time. Figs. 2-5 show some typical examples of random noise currents and the corresponding power spectra.

Fig. 2 shows a narrow-band power spectrum centered on frequency f_0 and extending from $f_0-\beta/2$ to $f_0+\beta/2$. The first thing the power spectrum shows about $I(t)$ is its rms value. Since $\overline{I^2(t)}$ is given by the area under the $w(f)$ curve, and since this area is $w_0\beta$, then

$$\text{rms } I(t) = \sigma = (w_0\beta)^{1/2}$$

Also, since the power spectrum is concentrated around the mid-band frequency f_0, it indicates that $I(t)$ will behave much like a sine wave of frequency f_0 with a slowly fluctuating amplitude or envelope. This behavior is shown in Fig. 2. The narrower the band, the more slowly the envelope fluctuates. In fact it may be shown that the envelope may be expected to have about 0.64 β maxima per second.

Why does the envelope fluctuate? One way of answering this question is again to regard $I(t)$ as consisting of an infinite number of sine waves all beating together. The fluctuations in amplitude are due to the alternating periods of interference and reinforcement. When only two sine waves of slightly different frequency beat together the periods of interference and reinforcement follow each other with perfect regularity, but when the infinite number of sine waves of $I(t)$ beat together they give the irregular pattern of random noise.

Fig. 3 shows a low-frequency power spectrum. Here $I(t)$ must fluctuate rather slowly because it does not contain any high-frequency components. Its oscillations are more irregular than those of narrow-band random noise because the "envelope" is fluctuating almost as fast as is the wave itself. Fig. 4 shows a wide-band power spectrum which extends down to zero frequency. Here the fluctuations of $I(t)$ are much more rapid than in the case of Fig. 3, but the degree of irregularity is about the same. In fact, the two cases are really the same statistically except for a change in the time scale.

Fig. 5 shows a general type of power spectrum which may be roughly divided up into two parts; a low-frequency portion and a high-frequency portion. The low-frequency portion gives the slow, large-amplitude fluctuations of $I(t)$ while the high-frequency portion contributes the rapid, small fluctuations which are superposed on the slower variations.

It is hoped that the curves drawn for Figs. 2, 3, 4, and 5 are true enough to life to give an idea of how the appearance of a random noise current is affected by the shape of its power spectrum.

The Autocorrelation Function

An important function associated with a given noise current is its autcorrelation function. The autcorrelation function $\psi(\tau)$, is defined as the time average of the product $I(t)I(t+\tau)$ and is a function of τ.

$$\psi(\tau) = \overline{I(t)I(t+\tau)} = \underset{T\to\infty}{\text{Limit}} \frac{1}{T}\int_0^T I(t)I(t+\tau)dt$$

$\psi(\tau)$ is much like the correlation coefficient in statistics. One of the classical examples used to illustrate the correlation coefficient is the relation between the heights of fathers and sons. Suppose measurements are obtained of the heights of 1,000 men and their fathers. If y_n is taken to be the height of the nth son and x_n the height of his father, and the measurements plotted on the (x,y) plane, a scatter diagram is obtained consisting of 1,000 points. The center of the cloud of points will be at $(\bar{x},\bar{y})$ where $\bar{x}$ and $\bar{y}$ are the average heights of the fathers and sons. The correlation coefficient of the distribution is defined as

$$r = \frac{\text{Ave}(x_n-\bar{x})(y_n-\bar{y})}{\sigma_x \quad \sigma_y}$$

where σ_x and σ_y are the standard deviations of the heights of the fathers and sons. In this particular example, the coefficient r is positive because tall fathers are likely to have tall sons and short fathers are likely to have short sons both of which tend to make $(x_n-\bar{x})\ (y_n-\bar{y})$ positive more often than negative.

For the case of random noise, set

$$x = I(t),\ \bar{x} = 0,$$

$$y = I(t+\tau),\ \bar{y} = 0$$

Averaging $I(t)I(t+\tau)$ over the interval from 0 to T is something like averaging $(x_n-\bar{x})\ (y_n-\bar{y})$ over the 1,000 pairs of sons and fathers. $\psi(\tau)$ measures the correlation between samples of noise taken at two times which are τ seconds apart. When τ is small, the correlation is high and $\psi(\tau)$ is relatively large. When τ is large, the correlation (for random noise) is small and $\psi(\tau)$ tends to zero. It should be pointed out that the autocorrelation function is not quite the same as the correlation coefficient. For instance, the maximum value of r is unity, whereas the maximum value of $\psi(\tau)$ is

$$\psi(0) = \overline{I^2(t)}$$

There is a remarkable relation between the power spectrum and the autocorrelation function, namely, one is the Fourier cosine transform of the other:

$$\psi(\tau) = \int_0^\infty w(f) \cos 2\pi f\tau\, df$$

$$w(f) = 4\int_0^\infty \psi(\tau) \cos 2\pi f\tau\, d\tau$$

When either $w(f)$ or $\psi(\tau)$ is known, then the other one can be obtained—by numerical integration if need be. These equations are sometimes called the "Wiener-Khintchine" relations. They are of considerable importance in solving practical problems. For example, it is often of interest to compute the power spectrum of the noise appearing in the output of some nonlinear device, such as a detector or amplifier, when the input consists of a signal plus noise. In such problems it is usually much easier to compute the autocorrelation function first and then obtain the power spectrum by integration.

Probability Distributions

Finally, the probability distribution of the values of $I(t)$ will be considered. One of the most important properties of a random noise current is that its instantaneous values are distributed according to a normal or Gaussian law. This fact is often used in computing the interference produced by noise. Suppose a time t_1 is chosen at random. Then the probability that $I(t_1)$ will lie between I and $I+dI$ may be shown to be

$$\text{Probability } [I<I(t_1)<I+dI] = \frac{dI}{\sigma\sqrt{2\pi}} \exp\left[-\frac{I^2}{2\sigma^2}\right]$$

where the standard deviation (the rms value of $I(t)$) is given by

$$\sigma^2 = \overline{I^2(t)} = \int_0^\infty w(f)df$$

It is important to note that the distribution of the instantaneous values of $I(t)$ does not depend on the shape of $w(f)$. The distribution depends only on the area under the $w(f)$ curve. This fact is somewhat surprising. It says that even though $I(t)$ may have the different appearances shown in Figs. 2–5, it is always normally distributed. For this reason it is often called "Gaussian noise," the terms "Gaussian distribution" and "normal distribution" being synonymous. This does not mean that all noises which have a power spectrum are Gaussian. An example to the contrary is a telegraph signal composed of marks and spaces chosen at random, the marks having a value of +1 and the spaces −1. This signal has a well-defined power spectrum but its values are limited to +1 and −1.

A distribution which is often confused with that of $I(t)$ is that of its envelope $R(t)$. As shown in Fig. 2, the envelope is of significance in problems involving noise in a narrow frequency band. $R(t)$ is also of importance because it represents the audio-frequency output of a radio detector when the input is radio-frequency noise. Choose a time t_1 at random and observe the value $R(t_1)$ of the envelope at that time. The probability that it will lie between the values R, $R+dR$ (chosen beforehand) may be shown to be

$$\text{Probability } [R<R(t_1)<R+dR] = \frac{RdR}{\sigma^2} \exp\left[-\frac{R^2}{2\sigma^2}\right]$$

where σ is, as before, the rms value of $I(t)$. R is never negative. This distribution is sometimes called the "Rayleigh distribution." Its integrated form is especially simple:

$$\text{Probability } [R<R(t_1)] = \exp\left[-\frac{R^2}{2\sigma^2}\right]$$

It will be observed, that just as in the case of $I(t)$, the distribution of $R(t)$ does not depend upon the shape of the power spectrum; it depends only on the area under $w(f)$. Fig. 6 shows the two probability distributions, the normal one for $I(t)$ and the Rayleigh for its envelope $R(t)$. The horizontal axis is marked off in units of σ, the standard deviation of $I(t)$.

A Flat-Bed Facsimile Telegraph Transmitter

W. D. BUCKINGHAM
NONMEMBER AIEE

AN experimental flat-bed facsimile telegraph transmitter with a number of novel features has been developed at the Water Mill Electronics Laboratory of The Western Union Telegraph Company. In the new machine, the message is placed on the flat bed of the transmitter and scanned by a series of closely spaced transverse lines as the sheet is advanced over the scanning line.

Such a device has several advantages over the more common type of facsimile transmitter which requires the message to be wrapped around a drum. With the flat-page or flat-bed transmitter, the message sheet requires no preparation or manipulation by the operator. It is simply laid on a table or dropped in a slot from which it is drawn by rollers through the machine. Furthermore, the sent message may be of any length. For example, copy from a telegraph teleprinter can be fed directly and continuously into the transmitter.

Optical System

The arrangement of the basic parts of a new machine is shown in the diagram of Fig. 1. Scanning is accomplished by sweeping a spot of light, 0.01 inch in diameter, horizontally across the message sheet from left to right at a uniform speed, and returning the spot quickly, at nineteen times the forward speed, to the left margin to repeat the cycle again and again as the message is advanced slowly at a uniform speed transversely across the scanning line. Light reflected from the message is collected by a cylindrical reflector, concentrated on a photocell, and converted into electric currents whose intensities are proportional to the reflected light at each instant.

TUNGSTEN ARC LAMP

The scanning light source is a miniature tungsten arc lamp, Fig. 2, developed specifically for facsimile use. It has a tungsten ball cathode, 10/1,000 inch in diameter supported on the end of a 4/1,000-inch-diameter tungsten wire, and a molybdenum disk anode. These two elements are mounted in a small glass bulb filled with argon gas.

The lamp operates from a special rectifier power unit which first delivers a high-voltage pulse to start the arc and then supplies a direct current of about 100 milliamperes at 40 volts to maintain the arc.

During operation the tungsten ball is maintained at incandescence by the heat of the arc to produce an extremely small, uniformly bright, stable, and well-defined point source of light. It can be focused with a single lens or mirror directly on the message in the facsimile transmitter without the use of the condensing lenses and pin-point aperture such as are required to produce an effective point source from the ordinary tungsten filament lamp usually employed in a "flying spot" scanner. The elimination of these elements by the use of the new lamp avoids

expensive optics, results in a brighter scanning spot and reduces the length of the optical path.

The new tungsten arc lamp offers an additional advantage over the tungsten filament lamp for facsimile transmitter use in that the light output of the tungsten arc is relatively constant with changes in lamp current. This comparison is shown by Fig. 3. A 10-per-cent (%) increase in current causes the light output of the tungsten filament lamp to increase 93%. Under a similar current increase, the light output of the tungsten arc lamp increases only 7%. Thus, it is not necessary to operate the tungsten arc lamp from a voltage regulator as is required for the tungsten filament lamp in this service.

During the life of the tungsten arc lamp, the tungsten ball gradually evaporates until it is reduced to the diameter of the supporting wire. This occurs after 200 to 300 hours of use. The lamp can then be renewed by reversing the polarity and sending ten times normal current through it for an instant so as to form a new tungsten ball on the end of the wire. This cycle can be repeated several times before the lamp is discarded.

ROCKING MIRROR

In the new flat-bed transmitter, light from the tungsten arc is collected by a concave spherical mirror which then reflects the image of the incandescent tungsten ball in the lamp as a small bright spot of light on the face of the message. This mirror is a simple plano-concave lens, $1^3/_8$ inches in diameter, whose concave spherical surface has been coated with aluminum to form a concave mirror with a 20-inch radius of curvature. The mirror is placed so as to be substantially equidistant from the light and its image. Thus the optical system works at unity magnification and the high focal ratio of $14^1/_2$. Under these conditions it is possible to produce a very high-grade image of the source with very low-cost optics. Flat mirrors are interposed in the optical path between the lamp and the concave mirror, and again between the concave mirror and the message, to direct the light beam back and forth so as to reduce the over-all space required for the optical beam.

The concave mirror is mounted on supports so that it can be rocked through an 11-degree arc by a motor-driven cam. This motion causes the image to sweep across the message at a uniform speed during 95% of the time of one revolution of the cam and to return to the starting point in the remaining 5% of the time. The cam is made of nylon impregnated with molybdenum disulfide. This material combines the advantages of quiet operation and long life of the nylon with the low friction properties of the molybdenum compound. The mirror mount is made of aluminum that it may have little mass. As a result, it has been found possible to operate such a rocking mirror at speeds up to at least 30 times a second or 1,800 rpm. The cam-operated mirror with the associated motor, light chopper, speed-reducing gears, and clutch of a unit which operates at 180 rpm, is shown in Fig. 4.

CYLINDRICAL MIRROR AND PHOTOCELL

While the spot of light scans the message from left to right for a distance of about 8 inches and returns quickly to repeat the cycle, the message is advanced transversely across the scanning line at a speed which produces 100 scanning lines to the inch of the message sheet. As the spot scans across the sheet, the light reflected from the message is collected by a cylindrical reflector and brought to a focus as a line of light on the photocell cathode.

The photocell is of a type which has a long, narrow, light-sensitive surface so as to pick up as much as possible of the line of light generated by the cylindrical reflector. With this combination of cylindrical reflector and photocell, the whole length of the photo-cathode collects light all of the time regardless of the position of the spot of light along the scanning line and thus avoids the usual requirement for such service that the photo-cathode be equally sensitive at all points.

The cylindrical mirror collects the reflected light over an average solid angle of more than 90 degrees. If the reflected light is assumed to have a Lambert cosine spatial distribution, it can be shown that the cylindrical reflector collects more than 50% of the total reflected light. This collecting system is so efficient that an ordinary gas photocell provides ample signal output.

If the message being sent through the new machine is narrower than the scan line length, the scanning spot falls on a cylindrical mirror back of the message during the part of its sweep when it is off the message. This mirror sends the light into a photocell which operates to blank the inverter signal. This arrangement automatically provides a white background over the entire width of the received copy regardless of the width of the transmitted message.

Electrical System

A chopper wheel interrupts the light from the lamp at 2,700 cycles per second to produce a modulated signal from the photocell that can be handled by an a-c amplifier. This 2,700-cycle carrier frequency is sufficiently high to transmit the 1,200-cycle frequency produced by the 180-rpm scanner. A 5,400-cycle chopper is used on 360-rpm machines.

A resistance-capacity coupled amplifier is used to amplify the modulated signal from the photocell. The amplifier is equipped with a time-delayed automatic volume control which holds the output of the amplifier constant within 1/10 decibel as the input changes slowly over a 10-decibel range. This arrangement assures that the amplifier, over its range of control, will produce a constant signal from the message background, regardless of its color. Thus the amplifier adjusts itself automatically to the correct gain to produce a copy from the recorder which will have a white background and yet not fail to record light copy such as pencil marks that may be on the original message. The photocell, cylindrical reflector, and amplifier assembly are shown in Fig. 5.

Mechanical System

The various elements of the flat-bed scanner may be selected and arranged

in any convenient form to fit the requirements of the particular service in which it is to be used. Fig. 6 shows a machine designed to handle copy up to $8^1/_2$ inches in width for private-wire service. In use, the message is placed on the flat table of the machine with the feed roller resting directly above the part of the message at which transmission is to start. A pointer at the edge of the table is adjusted to the line on the message where transmission is to end. If a message longer than the standard 11-inch sheet is to be sent, the end-of-message pointer is drawn to the extreme end of its travel. The machine will then transmit the copy, whatever its length, until the end of the sheet has passed the scanning line.

When the machine starts, the sheet is fed at high speed to bring the message quickly to the scanning line. The rate of feed is then reduced to normal during transmission and at the end is again increased to feed the message sheet into the "sent" message compartment.

A flat-bed machine designed for Western Union concentrator service is shown in Fig. 7. Here, standard length 8- or $8^1/_2$-inch-wide telegrams are dropped into a slot on the front of the transmitter. If the message does not fill the entire message box, an indicator bar set just below the signature will cause the machine to terminate the transmission at that point. When the start signal is received, the message is time-stamped on its face automatically and then fed at high speed to bring the top of the message box to the scanning line. At the end of the transmission, the sheet is fed at high speed into the sent message box at the bottom of the machine.

Since the new experimental flat-bed transmitters require little of the operator, it becomes possible to equip the new transmitters with automatic message loaders. The operator then puts the messages to be sent into the automatic loader and it in turn delivers the messages to the transmitter as required, one at a time and in sequence. Such a device is under development.

Although models have been made of the transmitter described here, further experimentation and considerable laboratory and field testing will be done before any decision is made to undertake production of this type of Telefax device. Evaluation studies based on such tests are now in progress.

Application of a Digital Computer to the Design of Power Transformers to Specification

C. L. MOORE
ASSOCIATE MEMBER AIEE

W. T. DUBOC
ASSOCIATE MEMBER AIEE

P. A. ZAPHYR
NONMEMBER AIEE

MOST power transformers of 1,000 kva and larger are built to specification, and the problem of reducing the amount of time required to produce designs for them has been acute for many years. In early 1954, this problem became the focus of attention because of increasingly critical performance requirements which actually lengthened the time required for design while at the same time demands for shorter building cycles were becoming more and more pressing. Furthermore, developments in core steel and insulation increased the need for comprehensive studies of the effects of these improved materials on the economics of transformer design and construction. Such studies can be made on a theoretical basis. They can also be made by changing individual parameters (e.g., cross-sectional area of the core) and calculating the effect of this change on the transformer characteristics. However, neither of these methods is a wholly satisfactory substitute for making a series of designs all of which meet the same requirements, with one exception (e.g., noise level) which is varied over a specified range. Because a given charcteristic may have a greater effect on one rating than on another, the number of designs which must be made necessarily covers a wide range of ratings and is quite large. Not only is such a project expensive, tedious, and time-consuming, but the problem of consistency is acute since no two engineers will use exactly the same margins; in fact, the amount of margin which a single engineer thinks necessary may vary over a period of time.

One solution to the problem of reduction in design time seemed to lie in the possibility of programming a digital computer to produce designs with no more input than the specifications normally given a design engineer. The growing availability of such machines made an investigation of this possibility feasible.

At the outset, there was little experience on which to base the approach to such a project. There seemed to be two avenues available, both involving certain sizable disadvantages. The first, adaptation of the trial-and-error method used by the design engineer, in effect, would involve programming the engineer's judgment and experience into the computer. The second and much more ambitious procedure was a completely fresh approach to the whole design problem. In this case, one function such as cost would be selected as critical and, through use of techniques similar to those of linear programming, the design parameters (e.g., copper size and core dimensions) would be adjusted to minimize this function consistent with meeting the guaranteed specifications. However, any function such as cost which might be selected is an extremely complicated and, usually, nonlinear function involving all parameters, many of which are discontinuous. Copper strap, for example, is available only in discrete sizes. Furthermore, the necessary nonlinear programming techniques were not fully developed.

After consideration of these factors, it was decided that the more desirable approach was the adaptation of the design engineer's technique. Primarily responsible for this decision was the consideration that the problem was of sufficient urgency as to make a solution desirable in the foreseeable future. Furthermore, one of the main reasons for the project was the determination of the feasibility of using a digital computer in the commercial design of custom-built apparatus. As the project progressed, these two criteria, feasibility and the time element, were largely the basis for several decisions made. A second example is the limitation of the ratings to which the program would be applicable by the following restrictions:

1. Three-phase.
2. One thousand to 15,000 kva, inclusive.
3. High-voltage winding basic impulse level (BIL): 110 kv to 350 kv, inclusive.
4. Low-voltage winding BIL: 95 kv maximum.
5. Two windings.
6. No-load taps on high-voltage winding.

The activity of units covered by these restrictions is high and a method for reduction in design time was desired.

Preliminary Steps

The trial-and-error method of design involves an initial selection or assumption of parameters (e.g., copper strap and core dimensions) necessary to the calculation of the performance characteristics. Once calculated, these characteristics are compared with those specified. In general, this comparison will reveal a discrepancy between the two. The initial assumptions are then revised and the process is repeated as many times as necessary until an acceptable design is produced. In most cases, the specifications such as loss guarantee impose only upper limits on the characteristics of the transformer design while the lower limits result solely from the necessity of minimizing cost and weights; an exception is impedance which must be met within plus and minus limits. The final design is therefore one which, in the judgment of the engineer, minimizes cost and weight, yet has sufficient margin to allow for manufacturing variation and inherent inaccuracies in the basic data and which will also meet all restrictions and limitations imposed by the factory and the standards. The problem of consistency of designs mentioned previously arises from this large factor of judgment.

Adapting the method described to a computer is not a simple task. The first step is to make a mathematical outline complete with all necessary equations and logical decisions. The latter includes the comparisons of calculated results to guaranteed specifications and the steps to take in case of agreement and disagreement. In the following paragraphs points of particular importance are summarized.

Use of an expensive computer could be justified only, if the computer program were complete in itself with no intermediate logical decisions or interpretation required by an engineer or operator. For this reason the input to the machine, in addition to the program and the data concerning material characteristics, limitations, and dimensions which it incorporates, is as follows:

Paper 56-79, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 24, 1955; made available for printing December 12, 1955.

C. L. MOORE is with the Westinghouse Electric Corporation, Sharon, Pa.; W. T. DUBOC is with the Westinghouse Electric Corporation, Boston, Mass., and P. A. ZAPHYR is with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

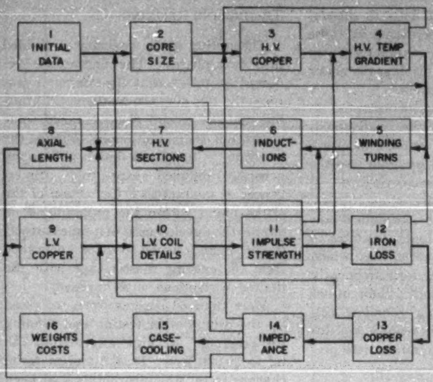

Fig. 1. Flow chart of computer program

1. Self-cooled and forced-air kva ratings.
2. High-voltage and low-voltage winding basic impulse levels.
3. Number and specified voltages of high-voltage winding taps and specified voltage of low-voltage winding.
4. High-voltage and low-voltage winding connections (delta or wye).
5. Noise level.
6. Temperature rise.
7. No load loss.
8. Exciting currents at 100% and 110% rated voltage.
9. Total loss.
10. Impedance.
11. Insulation space factor.
12. Eddy loss factors for high-voltage and low-voltage windings.

Items 1 to 10, inclusive, together with the restrictions just mentioned, define the operating characteristics of a transformer and are essentially the same as those received by the designer when he is given the job of designing a transformer. Item 11 was included because it is subject to possible slight variation from time to time, and item 12 was included because the method of calculating these factors was undergoing major revision at the time the program was developed.

It is evident that the initial values assumed for the various design parameters will have a considerable bearing on the number of repetitive trials (i.e., iterations) required to converge to an acceptable design. A design engineer usually has a wealth of previous designs from which he can select one with characteristics quite close to those of his current problem. It was considered impractical and expensive to store this tremendous number of data within the computer, so a substitute was developed in the form of a series of empirical equations based on a survey of recent designs covering the range of ratings to which the program was applicable. The most important was an equation for "Gross N" (defined as the product of the cross-sectional area of the core and the area of the core opening) as a function of the kva and BIL of the transformer.

The form in which basic data are most readily used by a designer is not the same as that which is most economical in terms of computer storage, and a large amount of adaptation was necessary. In general this involved development of equations to fit curves and tables wherever possible. In the case of data in discrete steps (e.g., sizes of copper strap), the tables were reduced to the minimum necessary.

In performing the iterative procedure of design, an engineer's judgment permits him to make partial calculations and adjustments in several parameters at once. For instance, he may know from experience that in a certain range of ratings, the no-load loss may govern induction whereas in another range, the noise level may be the determining factor. In another case he may know intuitively that a particular adjustment of a parameter which might be correct for, say high impedance cannot be used because it will result in high loss. The logic of a machine is such that it is restricted to a series of individual "either-or" decisions and it has no intuition at all, so the outline was prepared to allow for all possible contingencies. Also each time an adjustment in a parameter is made, all the characteristics which this parameter affects must be recalculated and retested against guaranteed values. This was perhaps the major problem. The final solution is best described by reference to Fig. 1, which is a block diagram of the flow of calculations through the program. From this it may be seen that, following establishment of design parameters in blocks 1 through 10, the first major characteristic which is calculated and tested is the impulse strength of the windings, block 11. If the design will meet the required impulse levels, the program proceeds to the calculation of iron loss. If it will not, corrections are made in one or more parameters as necessary, and previous calculations which are affected are recalculated. This process is repeated as many times as necessary until a design is obtained which will meet the required BIL. It should be noted that no consideration is given to other characteristics until the BIL requirement is satisfied, and this philosophy prevails through the program. The order in which the various characteristics are calculated was selected so that those least likely to fall outside the guarantees, under conditions defined by the initial assumptions and as determined from experience, are calculated first. The problem of oscillation described in the following was found to be reduced through use of this approach.

It is apparent from Fig. 1 that a given set of specifications may require a large number of iterations while the program converges to an acceptable design. During this process the problem of oscillation due to over-compensation may arise. For example, a given cross-sectional area of core may yield a design which meets all requirements except impedance, which is too low. To compensate, the area of the core may be decreased by one standard step but this, is turn, may result in an impedance which is too high. If this is compensated by increasing the area of the core by one step, oscillation may occur, since the original conditions will result. To prevent this from happening, the program is designed to test for return to the previous conditions, and should this happen that particular method of compensation is blocked and an alternate used.

To prevent overdesign (i.e., excessive margins) the program incorporates methods which will automatically attempt to design to maximum losses consistent with sufficient margins to assure that the resultant transformer will meet the required guarantees.

Once the mathematical outline and the supporting flow charts were developed, it was hand-tested. Recently designed typical transformers were selected and new designs were produced by working through the program by hand. This testing was of particular value in demonstrating inadequate consideration of possible contingencies as well as simple errors and omissions. The intermediate results obtained through this procedure were invaluable in later testing the computer program.

Computer Program

Having completed the preliminary steps of outlining, flow-charting and hand-testing the calculations, the way was prepared for programming a digital computer essentially to assume the role of a design engineer in processing a power transformer design.

CHOICE OF COMPUTER AND CODING SYSTEM

It was presupposed in preparing the mathematical outline that a stored program computer with large storage facilities would be employed. With the entire program in storage, the computer can choose among several alternate paths depending on the outcome of a prior calculation. Thereby, the flow required by the mathematical outline can be executed without external assistance. The IBM type-*701* computer was selected since it satisfied the requirements, in addition to being available on a service basis.[1]

Instead of coding the *701* in terms of its own language, it was decided to use a *701* interpretive routine, called Speedcode.[2] Speedcode permits one to perform all calculations without keeping track of the position of the decimal point, normally a cumbersome and time-consuming operation. It also provides the elementary functions (e.g., sine, logarithm), automatic checks, and other features designed to simplify the coding and testing of the program. These features, however, are achieved at the expense of increasing the calculation time. The decision to use Speedcode was based on the desire to establish the feasibility of the project in a reasonable length of time.

CODING

The *701* retains digital information in three different types of storage units: magnetic tapes, magnetic drums, and electrostatic tubes. Calculations can be performed only on numbers stored in electrostatic storage, so information on tapes and drums must be moved into electrostatic storage before being used.

It was apparent from the outset that the coding would be too large to be stored entirely in electrostatic storage and that it should be subdivided into smaller parts or subprograms. Toward that end, the program was separated into 16 subprograms, the divisions occurring at those points to which the flow could return in an iterative path. Fig. 1 displays the major subdivisions of the program.

Three features were incorporated in the organization of the coding: 1. Efficient utilization of storage facilities. 2. Fast-loading of the program into the computer by means of magnetic tape. 3. Simple running procedure.

As the coding of the mathematical outline progressed, it was found desirable to construct a set of subroutines which could be called on to perform frequently needed special functions. Subroutines for searching tables, for rounding calculated values to integer values, and for evaluating often-used equation were prepared.

To obtain the features of the program just mentioned the *701* storage is employed in the following manner:

1. In addition to being the working storage of the computer, electrostatic storage contains information required by almost all of the 16 subprograms. Included are 1. the input data listed in the section "Preliminary Steps"; 2. the rounding subroutines; 3. often needed constants; and 4. a set of electrostatic storage locations used to direct the flow, keep track of the number of iterations, and prevent nonconverging oscillations.

2. Magnetic drums contain the remaining subroutines, the tables, and the intermediate results.

3. One magnetic tape contains all 16 subprograms which are moved singly into the working area of electrostatic storage as called for by the flow. That tape also contains all information required initially by the drums and electrostatic storage, i.e. tables, subroutines, and constants. Therefore, it is the high-speed means of loading the program into the computer. Since the entire program is contained on that master tape, it must be preserved between runs.

4. Punched cards provide the primary source of information to the *701*. A set of cards is used in the program to load the design input data listed previously, and to transfer control to the master tape.

The master tape on receiving control first distributes the tables, subroutines, and constants to the drums and electrostatic storage as required. It then moves the first subprogram into the working area of electrostatic storage and causes control to transfer to that subprogram. From there the flow proceeds as directed by the mathematical outline. Since the master tape assumes the major role in starting the calculations, the operator need only place that tape in the proper unit and load the initial set of cards.

TESTING AND REFINING

The testing of the coding was divided into two phases. The first phase required assurance that the computer was properly following the mathematical outline and the second phase entailed some changes in design philosophy to refine the program. Changes in design philosophy generally entailed expediting convergences on guarantees. Correction of the errors found within the program necessitated the development of a tape correcting program designed to write a new tape from the existing master tape with the desired corrections superimposed.

More than 50 designs were processed by the computer in testing and refining the program. Ratings ranged from 750 up to 20,000 kva. Design and material changes were also incorporated to keep the program abreast of current design methods and to obtain experimental data.

DESCRIPTION OF FINISHED PROGRAM

The entire program of 3,600 Speedcode instructions and 1,000 data items is contained on a single magnetic tape. To process an order one simply punches the input data into six cards which, along with a deck of about 20 cards, are loaded into the *701*. From then on, the computer takes over completely, and in a matter of minutes prints out the same results previously obtained after days of effort by a design engineer. The computer also prints out enough information so that one can see exactly what calculations and iterations were performed in producing the design. In addition, a cost analysis is performed automatically at the end of each design.

The ease of running the program is evidenced by the fact that *701* computer operators were able to run designs completely with only one sheet of simple instructions. Designs have also been produced and revisions inserted on the master tape by using a transceiver link between the engineering offices and the computer installation. The transceiver is a device which can transmit and receive information in the form of punched cards by way of standard telephone circuits.

Before any computer design program can take an active role in the manufacturing process, it is imperative that some ready means be available to keep the program up to date with current developments in design procedure. For that reason the tape-correcting routine with its ease of operation forms an integral part of the transformer design program.

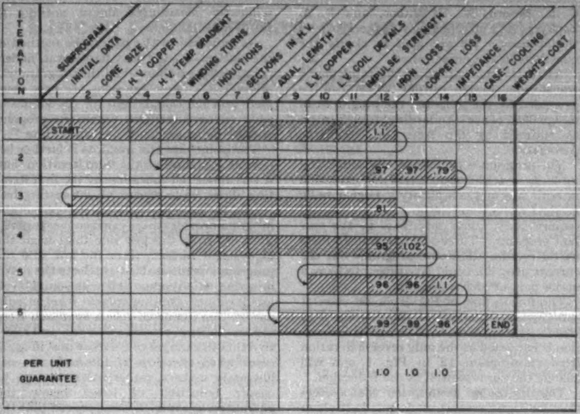

Fig. 2. Example of computer design

Example Showing Iterations

The design philosophy incorporated within the program can be demonstrated by following the iterations of a sample design. The iteration bars of Fig. 2 follow the flow as the computer iterates along the paths of Fig. 1 to design a 5,000-kva transformer with BIL of 350 kv. This example was chosen to demonstrate a variety of iterations taken to converge on design levels of losses and impedance. The first iteration found that the initial design exceeded the design level of iron loss in subprogram 12 by approximately 10%. To decrease the losses below the guaranteed values, the computer returned to subprogram 5 which lowered the induction by increasing the number of turns. On the second iteration both loss conditions were satisfied but the calculated impedance was only 79% of the guarantee. That low impedance necessitated a return to subprogram 2 where the core size was decreased, thereby increasing both turns and impedance on the following iterations. In this case the increase of turns resulted in iron losses below economically acceptable values, so a fourth iteration was taken to adjust the turns raising the iron losses nearer to the guarantee. However, high copper losses required a return to increase the copper size. The fifth iteration resulted in an impedance 10% over the guarantee. That slightly high impedance was corrected by a change of physical proportions during the sixth iteration and the design was completed. The computer time to accomplish this design including the cooling and cost calculations was 8.4 minutes. It should be noted that the computer has calculated many designs in less time with fewer iterations.

Analysis of Designs

The design program has successfully designed transformers within the range of 750 and 20,000 kva and with BIL including 350 kv. With an input of six punched cards the computer has determined the quantity, distribution, and design of materials totaling up to 94,000 pounds per unit. In general, the quality of the designs has proved excellent. The computer calculated designs have better balanced values of gradient and ampere-turn distribution than most comparable hand-calculated designs. Design time for the computer ranges from 3 to 12 minutes. This time could be materially reduced on some of the most recent digital computers.

Conclusions

Some of the results of significance to the engineering public and to the users and manufacturers of transformers are:

1. With only performance data as input, the computer automatically designs a transformer to meet all specifications in a 1-step process.
2. The 100-to-1 speed advantage of the computer decreases the engineering time requirements in processing transformer orders, thereby providing faster delivery.
3. A consistency of high-quality design is provided through the computer program which is based on the best engineering data available.
4. The use of computers in design will permit the manufacturer to pass benefits of new materials or new methods more rapidly to the user.
5. The development engineer has an opportunity to study the effect of varying any one parameter by obtaining from the computer a large number of consistent designs.
6. The use of computers will provide a fuller utilization of engineering manpower. By assuming routine design work, the computer can release design engineers from routine design to development work or further creative work.
7. The initial objective of providing the feasibility of automatic design was more than realized, and a valuable development and design tool has resulted.

Discussion

S. B. Williams and **P. A. Abetti** (General Electric Company, Pittsfield, Mass.): The authors are to be commended for their presentation. It would be interesting to know what percentage of the total power transformer design output can be processed with the use of the program described in the paper. Also, is this program suitable for extension to design units of larger size and complexity, and of higher basic insulation levels, e.g., 3-winding transformers and autotransformers?

To refer to Fig. 2, some steps are not very clear from the design standpoint. For instance, at the end of the third iteration it is found at routine 12 that the iron loss is 19% too low and the program switches to the induction routine (number 6). It is difficult to see how inductions can be changed while maintaining the same core size (routine 2) and the same winding turns (routine 5). In fact, change of the inductions will change the rated winding voltages which will no longer meet specifications. At the end of the fourth iteration, when it is found that copper loss is 2% high, an adjustment is made in the low-voltage winding only. This would seem to upset the balance between low-voltage and high-voltage winding rises. It is well known that optimum copper utilization may be obtained only when these rises are balanced.

Furthermore, it is not clear as to how a complete engineering design, as described by the authors in their oral discussion, can be obtained by establishing as fixed input data: 1. the insulation space factor, and 2. the eddy loss factor for the two windings. It would appear that these factors are not part of the customer's specifications or industry standards, which should be calculated from the actual dimensions of the core windings, rather than estimated in the initial stage. Unless the actual values coincide with the estimated values, the test results may not agree with the calculated results and with the customer's specifications.

It appears that the design in Fig. 2 does not converge smoothly and logically to the desired final answer. There are evident indications of overcompensation of certain characteristics which introduce abnormal oscillations. For instance, at the end of the first iteration the only characteristic which has been computed, the iron loss, is 10% off. After the third iteration the same characteristic, again the only one computed, is 19% off in the opposite direction. From this it would appear possible that under certain unfavorable circumstances, the design might oscillate back and forth about the desired value, without ever converging to that value. In the paper[1] presented by the discussers it was recognized that convergence must be determined to include all possible variables, and that appropriate damping factors must be established to avoid overcompensation. Fig. 2 of reference 1 shows clearly that oscillations are avoided in this manner. The question of convergence becomes more critical as the complexity of the design increases, the requirements become more exacting, and the number of design variables increase. Such is the case of 3-winding transformers and autotransformers for extra-high voltage with difficult tap arrangements in several windings which are included in the computer program we have described.[1]

1. APPLICATION OF DIGITAL COMPUTERS TO TRANSFORMER DESIGN, S. B. Williams, P. A. Abetti, E. F. Magnusson. *AIEE Transactions*, vol. 75, pt. III, 1956 (*Paper No. 56-80*).

C. L. Moore, W. T. Duboc, and P. A. Zaphyr: The discussion is appreciated by the authors. We are glad to clarify the questions in the order raised.

As to the percentage of the total power transformer design output which can be processed by the program, the program can design 62% of the standardized transformers as outlined by the American Standards Association.

The program is fundamentally sound and provides a sound foundation for extension in both size and complexity. Higher basic insulation levels and autotransformers would require only minor additions to the current program. Three-winding transformers would require additional programs but the current program could be utilized to form a major part of such a program.

The fourth flow of Fig. 2 should start at subprogram 5 instead of subprogram 6 as erroneously indicated. This 12-to-5 iteration is indicated as the only reverse iteration from subprogram 12 in Fig. 1 and will change the turns as well as the induction.

The discussers' assumption that corrections for high losses are made only in the low-voltage coil is unjustified, though admittedly such an inference might be drawn from Figs. 1 and 2. However, reduction of copper loss with constant turns maintained can be achieved by an increase in the thickness of the conductor which only affects the radial dimensions of the conductors and coils. Thus, reduction of losses in either winding can be accomplished by changes of radial dimensions only within subprogram 13 so that return to subprogram 10 is required simply to correct diameters and to verify that these changes did not adversely change the impulse strength and iron losses. The program maintains a very good balance of winding rises by reducing the losses of the winding with the higher calculated rise. An indication of the balance attained and the optimum utilization of copper is demonstrated by the values of the calculated winding gradients. In the example cited the high-voltage temperature gradient calculated to be 5.7 degrees centigrade and the low-voltage gradient to be 5.6 degrees.

Our term "insulation space-factor" has proved misleading. The term does not refer to any over-all ratio of insulation to conductor area as interpreted by the discussers, but merely indicates the compression factor which is applicable to the nominal value of the axial build-up of radial spacers in the high-voltage column. The inclusion of this factor was only for development consideration. In production designs it is loaded as 0.94 for all sizes and ratings and consequently contributes almost nothing to the design philosophy.

As indicated in the paper, the method of calculation of eddy loss factor was undergoing major revision when the program was originated. These revisions are now complete and the calculations for the values of eddy currents included within the program and are no longer loaded as input data.

The point that the iron loss is farther below the guarantee on the third iteration than it was above the guarantee on the first iteration allows us to discuss an interesting feature of the program. The philosophy of the program provides more rapid convergance of iron loss from the low side than from the high side. In fact, from the low side the program in almost all cases selects the maximum induction compatible with sound level, loss level and exciting current level in only one 12-to-5 iteration. This approach from the low side has proved so certain and effective that in changes of core size and in some cases when iron loss is too high, we deliberately make a rather coarse change to ensure reduction of losses below the guarantee, as experience has proved that the program will seek the optimum induction on the next iteration. Thus, oscillation about the iron loss guarantees have been of negligible concern with this program. Regarding the general problem of oscillation, it may be mentioned that the only point in the program at which this problem has arisen is in connection with the procedures designed to correct for high and low impedance. As pointed out in the body of the paper, the program is designed so that a continuous check is maintained as to whether or not oscillation is occurring. Since there are several ways to adjust a design in order to bring the impedance within tolerable limits, oscillation simply causes the machine to switch from the preferred to the first alternative method of correction. All that is lost is the time required for two iterations which is insignificant especially since the problem arises only infrequently. It should be noted that every characteristic required of a transformer design is similar to impedance in that the design parameters can be adjusted in several ways in order to make the calculated value equal the guaranteed value. Hence, should the problem of oscillation arise anywhere in the program, it can always be solved by the method described here and in the paper.

Linear Programming on an Electronic Analogue Computer

INSLEY B. PYNE
ASSOCIATE MEMBER AIEE

A GREAT deal of attention has been given in recent years to the computational aspects of linear programming. The reason for this development lies in the applications of the problem to such fields as operations research, game theory, logistics, military tactics, and others. The object of this paper is to present a method for performing linear programming on an analogue computer containing only standard components. The size of the problem that can be solved is limited by the number of computing amplifiers available and by the number of inputs to each amplifier. The method is unusually flexible because the computer constantly seeks new solutions as the parameters of the problem are varied.

An Optimization Problem

Although the method is capable of solving several types of optimization problems, it will be illustrated by a single type which can be stated in the following form. It is required to maximize the objective function of n variables

$$Z=\sum_{k=1}^{n}\frac{x_k}{\alpha_k} \qquad (x_k \geq 0) \tag{1}$$

subject to the m restrictions

$$\begin{aligned}&\sum_{k=1}^{n}\frac{x_k}{a_{1k}}\leq 1\\ &\sum_{k=1}^{n}\frac{x_k}{a_{2k}}\leq 1\\ &\sum_{k=1}^{n}\frac{x_k}{a_{mk}}\leq 1\end{aligned} \tag{2}$$

where the α's and a's are constants. The method described in this paper solves the problem with $(n+2m+2p)$ amplifiers, where

n = number of variables
m = number of restrictions
p = number of negative quantities among the a's

The reasons for using denominator coefficients will become apparent later.

Geometrical Interpretation

The variables $x_1, x_2, \ldots, x_n$ can be treated as the co-ordinates of a point in a Euclidean space of n dimensions. The point with these co-ordinates will be called the objective point. The objective function, equation 1, is continuous and single-valued everywhere within this space and therefore can be used to define a gradient (grad) vector, grad Z. If $\mathbf{i}_1, \mathbf{i}_2, \ldots \mathbf{i}_n$ are unit vectors in the directions of the co-ordinate axes, then

$$\text{grad } Z=\nabla Z=\sum_{k=1}^{n}\frac{\partial Z}{\partial x_k}\mathbf{i}_k=\sum_{k=1}^{n}\left(\frac{1}{\alpha_k}\right)\mathbf{i}_k \tag{3}$$

The vector ∇Z is everywhere constant, normal to the hyperplanes of equal Z, and in the direction of steepest ascent.

The jth restriction of equations 2 represents a hypervolume in the n-space bounded by the hyperplane

$$\sum_{k=1}^{n}\frac{x_k}{a_{jk}}=1$$

This bound is called the jth edge. An edge separates the region of the space in which an inequality is satisfied from the region in which it is violated. The space in which all of the given inequalities are satisfied is called the allowed region. The allowed region is ordinarily closed in the sense that the objective function cannot increase without limit without entering the restricted region. The scalar a_{jk} represents the intercept of the jth edge with the kth co-ordinate axis. Any of the inequalities, equation 2, are superfluous if its edge lies wholly within the restricted region.

Define a vector $\mathbf{N}_j$ normal to the jth edge and directed toward the allowed region. There are exactly m such vectors and each is associated with a particular restriction. To compute the components of $\mathbf{N}_j$, first note that the following linearly independent vectors are parallel to the jth edge. i.e., they are on the hyperplane

$$\sum_{k=1}^{n}\frac{x_k}{a_{jk}}=1$$

$$\begin{aligned}&(a_{j1}\mathbf{i}_1-a_{j2}\mathbf{i}_2)\\ &(a_{j2}\mathbf{i}_2-a_{j3}\mathbf{i}_3)\\ &(a_{jn-}\mathbf{i}_{n-1}-a_{jn}\mathbf{i}_n)\end{aligned} \tag{4}$$

The vector $\mathbf{N}_j$ has the properties that its inner product with each vector of the set, equation 4, vanishes and also that it is directed away from the jth edge toward the allowed region. Therefore it can be written as

$$\mathbf{N}_j=-\left(\frac{\mathbf{i}_1}{a_{j1}}+\frac{\mathbf{i}_2}{a_{j2}}+\ldots+\frac{\mathbf{i}_n}{a_{jn}}\right) \tag{5}$$

Next define m quantities $\delta_1, \ldots, \delta_m$, one for each inequality, such that

$$\begin{aligned}&\delta_j=0 \quad \text{when} \sum_{k=1}^{n}\frac{x_k}{a_{jk}}\leq 1\\ &\delta_j=1 \quad \text{when} \sum_{k=1}^{n}\frac{x_k}{a_{jk}}> 1\end{aligned} \tag{6}$$

Define the vector $\mathbf{f}$ as follows

$$\mathbf{f}=K \text{ grad } Z+\sum_{j=1}^{m}\delta_j\mathbf{N}_j \tag{7}$$

where K is a constant.

In terms of components, f may be written

$$\mathbf{f}=f_1\mathbf{i}_1+f_2\mathbf{i}_2+\ldots+f_n\mathbf{i}_n \tag{8}$$

From equations 3, 5, and 7 the kth component is

$$f_k=\frac{K}{\alpha_k}-\sum_{j=1}^{m}\frac{\delta_j}{a_{jk}} \tag{9}$$

Both the vector $\mathbf{f}$ and its kth component f_k depend on the co-ordinates of the objective point because of the presence of the δ's in equations 7 and 9.

Let the position of the objective point be described by the vector

$$\mathbf{r}=x_1\mathbf{i}_1+x_2\mathbf{i}_2+\ldots+x_n\mathbf{i}_n \tag{10}$$

The velocity of the objective point in the n-dimensional space may therefore be defined as the vector

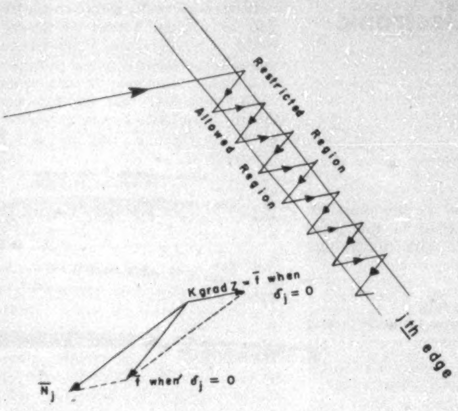

Fig. 1 (above). Motion of objective point in neighborhood of a restriction

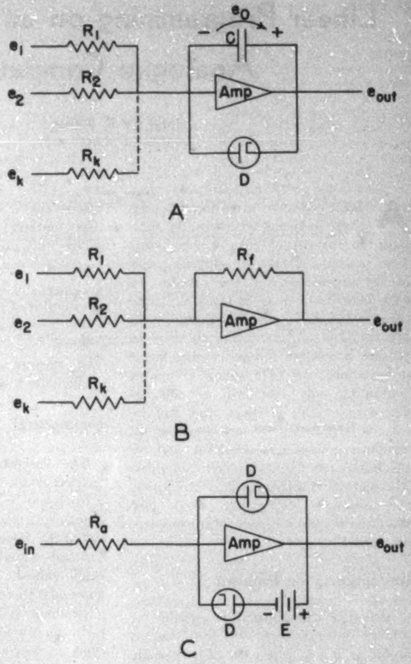

Fig. 2 (right). The three basic elements for linear programming

$$\mathbf{v}=\frac{d\mathbf{r}}{dt} \qquad (11)$$

where t is the time.

The equation which describes the method of this paper can now be written. Define a constant scalar γ such that

$$\frac{d\mathbf{r}}{dt}=\gamma\mathbf{f} \qquad (12)$$

Equation 12 describes the motion of the objective point as the solution is approached. The solution is to be the value which $\mathbf{r}$ finally attains. From equation 9 the kth component of equation 12 may be written

$$\frac{dx_k}{dt}=\gamma\left(\frac{K}{\alpha_k}-\sum_{j=1}^{m}\frac{\delta_j}{a_{jk}}\right) \qquad (13)$$

The objective point moves through the allowed region with a velocity γK grad Z, until it reaches a restriction such as the jth. At this point, the motion is determined by two vectors, the gradient and the vector $\mathbf{N}_j$ normal to the jth hyperplane. If N_j is greater than the normal component of K grad Z, the point will be ejected from the restricted region. The actual rebound is infinitesimal in magnitude as the objective point moves into the allowed region. The vector $\delta_j\mathbf{N}_j$ then vanishes, and the gradient causes the motion to reverse until the point again enters the restricted region. In this way, the objective point moves along the restriction boundary in the direction of the projection of the vector gradient Z on the jth hyperplane. This motion is shown greatly exaggerated in Fig. 1.

To prevent breakthrough into the restricted region, we must have

$$-K \text{ grad } Z\cdot\mathbf{N}_j<N_j^2 \qquad (14)$$

With the use of equations 3 and 5, this determines an upper limit on K

$$K<\frac{\displaystyle\sum_{k=1}^{n}\frac{1}{a_{jk}^2}}{\displaystyle\sum_{k=1}^{n}\frac{1}{a_{jk}\alpha_k}} \qquad (15)$$

which must be satisfied for every j.

Solution on Analogue Computer

To solve equation 13 on an analogue computer, it is necessary to divide the computer into the following three types of systems.

1. A set of n summing integrators limited to allow positive outputs only.
2. A set of m summing amplifiers, one for each restriction.
3. A set of m switches, one for each restriction.

The positive-output summing integrator is shown in Fig. 2(A) and, for positive e_{out} only, it satisfies the equation

$$e_{out}=-\frac{1}{C}\int\left(\frac{e_1}{R_1}+\frac{e_2}{R_2}+\ldots+\frac{e_k}{R_k}\right)dt+e_0 \text{ volts} \qquad (16)$$

where e_0 is the initial voltage across the condenser C. The diode D prevents the output from becoming negative.

The summing amplifier is shown in Fig. 2(B) and satisfies the equation

$$e_{out}=-R_f\left(\frac{e_1}{R_1}+\frac{e_2}{R_2}+\ldots+\frac{e_k}{R_k}\right) \text{ volts} \qquad (17)$$

The switch is shown in Fig. 2(C). Its properties are described as follows

$$e_{out}=0 \text{ volts} \quad \text{when } e_{in}>0 \qquad (18)$$

$$e_{out}=E \text{ volts} \quad \text{when } e_{in}<0$$

Fig. 3 shows the interconnection of n integrators, m summers, and m switches. The output of the kth integrator may be found by equation 16

$$e_k=-\frac{1}{C}\int\left(-\frac{\beta B_k}{R_k}+\frac{V_1}{r_{1k}}+\frac{V_2}{r_{2k}}+\ldots+\right.$$

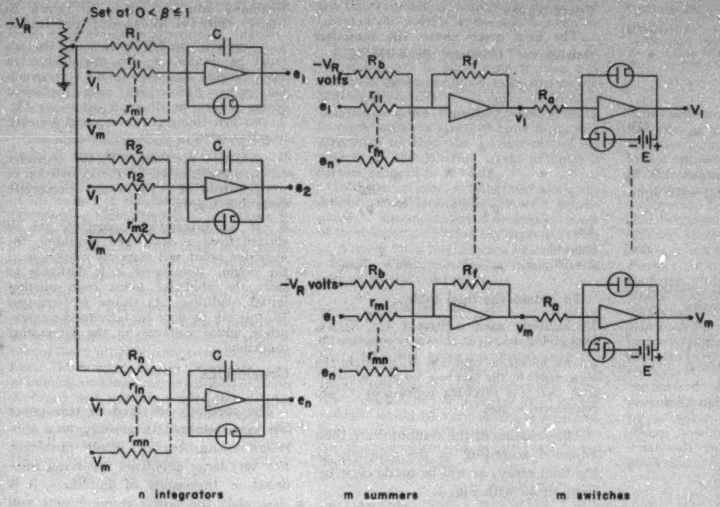

Fig. 3 (left). Connection of computer for linear programming

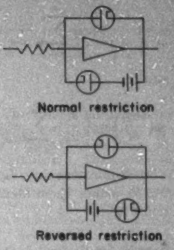

Fig. 4 (above). Alternate forms of switching device

$$\left.\frac{V_m}{r_{mk}}\right)dt \text{ volts} \qquad (19)$$

if the condenser C is initially discharged. The output of the jth summing amplifier is

$$v_j = -R_f\left(-\frac{V_R}{R_b}+\sum_{k=1}^{n}\frac{e_k}{r_{jk}}\right) \text{ volts} \qquad (20)$$

The jth switch has an output voltage V_j such that

$$V_j = 0 \text{ volts} \qquad \text{when } v_j > 0 \qquad (21)$$

$$V_j = E \text{ volts} \qquad \text{when } v_j < 0$$

Let δ_j be defined as follows

$$\delta_j = 0 \qquad \text{when } \sum_{K=1}^{n}\frac{e_k}{r_{jk}} \le \frac{V_R}{R_b} \qquad (22)$$

$$\delta_j = 1 \qquad \text{when } \sum_{K=1}^{n}\frac{e_k}{r_{jk}} > \frac{V_R}{R_b}$$

It follows that the output voltage of the jth switch is

$$V_j = \delta_j E \text{ volts} \qquad (23)$$

Differentiating equation 19 with respect to time, and introducing the symbolism just given, the equation which describes the computation performed by the circuit of Fig. 3 may be written

$$\frac{de_k}{dt} = \frac{1}{C}\left(\frac{\beta V_R}{R_k} - E\sum_{j=1}^{m}\frac{\delta_j}{r_{jk}}\right) \text{ volts per second} \qquad (24)$$

Equation 24, which describes the operation of the computer network of Fig. 3, is identical in form with equation 13, which describes the desired motion of the objective point of the function Z. Therefore, with proper selection of the computing resistors, the computer is properly connected to perform the computation of equation 13.

Completion of Analogue: Scaling

Each analogue computer operates best within the ranges of time and voltage which are implicit in its design. The following quantities, which determine these ranges, are associated with the computing equipment:

1. Integrating condenser C, microfarads.
2. Reference voltage V_R, volts.
3. Battery, E, volts.
4. Maximum allowable amplifier output voltage, $E_{\max}$, volts.
5. Range of computing resistances.

$R_{\min} \ldots R_{\text{mid}} \ldots R_{\max}$, megohms

A usual value for the integrating capacitors is 1 microfarad, except in high-speed repetitive computers, which use a value smaller than this.

The voltage E can be supplied by a dry battery and its value is not critical. The most convenient voltage is one that is of the same order of magnitude as the computer reference voltage. Since the battery draws negligible current, a small unit may be used.

The resistance R_{mid} can have a value anywhere within the upper middle part of the available range. Whatever value of resistance is recommended for use in the feedback and input paths of a sign-changing amplifier is a convenient choice. Alternately, R_{mid} may be chosen so as to make the product (CR_{mid}) either 1 second or some other convenient unit of time. On a computer using 1-microfarad integrating capacitors, a convenient value for R_{mid} is 1 megohm.

The resistance R_a is not critical, but it should be much larger than the forward resistance of the diodes. A convenient value is R_{mid}. The resistances R_f and R_j should be of the same order of magnitude as R_{mid}. Equation 20 shows that, if the e's are all initially zero, the output of each summing amplifier will start at $E_{\max}$ if R_f and R_b are chosen in the ratio

$$\frac{R_f}{R_b} = \frac{E_{\max}}{V_R} \qquad (25)$$

To establish the relation between equation 13 and its analogue, equation 24, define a set of scale factors S_k such that

$$e_k = S_k x_k \qquad k = 1, 2, \ldots, n \qquad (26)$$

Substituting for x_k in equations 6 and 13, these become

$$\delta_j = 0 \qquad \text{when } \sum_{k=1}^{n}\frac{e_k}{S_k a_{jk}} \le 1 \qquad (27A)$$

$$\delta_j = 1 \quad \text{when} \sum_{k=1}^{n} \frac{e_k}{S_k a_{jk}} > 1 \tag{27B}$$

and

$$\frac{1}{S_k}\left(\frac{de_k}{dt}\right) = \gamma\left(\frac{K}{\alpha_k} - \sum_{j=1}^{m} \frac{\delta_j}{a_{jk}}\right) \tag{28}$$

Multiplication of equations 27 by V_R/R_b makes them identical with equations 22 if

$$r_{jk} = \frac{R_1}{V_R} S_k a_{jk} \tag{29}$$

Substituting for a_{jk} from equation 29 into equation 28, we may write

$$\frac{de_k}{di} = \frac{\gamma R_b S_k^2}{E V_R}\left(\frac{KEV_R}{R_b S_k \alpha_k} - E \sum_{j=1}^{m} \frac{\delta_j}{r_{jk}}\right) \tag{30}$$

This is identical with equation 24 if

$$R_k = \mu S_k \alpha_k \tag{31}$$

where $\mu = \beta R_b/KR$

and also

$$\gamma = \frac{EV_R}{CR_b S_k^2} \tag{32}$$

Through the relations 29, 31, and 32 the analogy is now complete.

A convenient method for proceeding is as follows. Write an array, such as that for the unscaled problem below, which represents equations 1 and 2 of the original problem. In each column, select the largest coefficient, max a_{jk}, and determine the scale factor for that column from equation 29, using R_{mid} for the corresponding max r_{jk}

$$S_k = \frac{V_R R_{\text{mid}}}{R_b(\max a_{jk})} \tag{33}$$

Multiply each column in the table by itsscale factor, obtaining an intermediate form shown in the intermediate array.

ARRAY FOR UNSCALED PROBLEM

	x_1		x_n
N_1	a_{11}	…	a_{1n}
·	·		·
·	·		·
·	·		·
N_m	a_{m1}	…	a_{mn}
Z	α_1	…	α_n

INTERMEDIATE ARRAY

	$e_1 = S_1 x_1$	…	$e_n = S_n x_n$
	$S_1 a_{11}$	…	$S_n a_{1n}$
	·		·
	·		·
	·		·
	$S_1 a_{m1}$	…	$S_n a_{mn}$
	$S_1 \alpha_1$	…	$S_n \alpha_n$

FINAL ARRAY

The final array shows the computer resistances. Compare this with Fig. 3.

	e_1	…	e_n
V_1	$r_{11} = \frac{R_b}{V_R} S_1 a_{11}$	…	$r_{1n} = \frac{R_b}{V_R} S_n a_{1n}$
·	·		·
·	·		·
·	·		·
V_m	$r_{m1} = \frac{R_b}{V_R} S_1 a_{m1}$	…	$r_{mn} = \frac{R_b}{V_R} S_n a_{mn}$
Analogue of $Z = Z^*$	$R_1 = \mu S_1 \alpha_1$	…	$R_n = \mu S_n \alpha_n$

To obtain the final table:

1. Multiply each a-element by R_b/R_R, thus giving the r_{jk}, as shown by equation 29.

2. As shown in equation 31, multiply the α-elements of the last row by any constant μ so that the resulting resistances R_k are convenient in size.

The resistors of the computer are then adjusted according to the schedule of the final array, as will be made clear by comparison with Fig. 3.

In the expression $\mu = \beta R_b/KE$, the quantities R_b and E have already been selected. The factor K determines the magnitude of the influence of grad Z, as shown by equation 7, and hence influences the speed with which the machine approaches the solution. Once μ is fixed by the use of convenient values for the R_k, the potentiometer setting β, Fig. 3, determines the value of K. If K is made larger than the limit indicated by the relation 15, the objective point will break through a barrier. This can be detected by the overloading of an integrator, and can be corrected by reducing β.

The velocity of motion of the objective point is directly proportional to the factor γ of equation 12, which is given by equation 32.

Additional Aids to Computation

Various additional aids in computation are as follows:

1. To move an edge parallel to itself inward, lower the voltage which is applied to R_b of the corresponding summer from a value V_R to some smaller voltage; and to move it outward, raise the voltage applied to the corresponding summer and lower the corresponding resistance R_f proportionately to prevent saturation of the summing amplifier; see equation 25.

2. To minimize instead of maximize an objective function: apply $+V_R$ instead of $-V_R$ to the integrators.

3. To interchange the restricted and allowed regions for any restriction edge: reverse input and output terminals of the switching amplifier. This is shown in Fig. 4. Only two wires need to be changed.

4. Negative coefficients among the a's must be treated by the introduction of sign-changing amplifiers in the corresponding paths. Since each such coefficient enters the wiring diagram twice, see Fig. 3, two sign changers are required for each negative term.

5. Negative coefficients in the objective function are handled by the application of $+V_R$ instead of $-V_R$ at the appropriate integrator inputs.

6. If the integrating capacitors are all started from a discharged condition, the objective point will start its motion from the origin. Sometimes it is desirable to start the objective point from another initial condition. As shown by equation 16, this can be done by introducing appropriate initial voltages on the integrating capacitors.

Conclusions

The method described in this paper has been applied successfully to a considerable number of small problems. For very large problems involving hundreds or thousands of amplifiers, it is clear that the power requirements will become excessive. For such problems the development of solid-state amplifiers offers considerable promise. A special problem board would be convenient. Since each resistance among the a's enters the problem twice, these could be combined in a linear programming computer so that both are set in a single operation. The entire computer could be internally wired, and its programming board would then be a set of knobs arranged and marked as in the final array given previously.

However, in its present form, problems of moderate complexity can be solved readily on commercially available computers. Even problems involving certain types of nonlinearities may be introduced without drastic alteration of the method. The flexibility inherent in the method will perhaps be of benefit in guiding the intuition of the theorist in the field of optimization.

◆

Discussion

Philip Wolfe (Princeton University, Princeton, N. J.): The computational method Professor Pyne has developed promises to increase greatly the utility of the linear programming formulation of certain classes of operational problems.

Its use seems to be supplementary to that of the simplex method of George Dantzig, designed for use on digital computing machinery for the maximization of a linear function of variables subject to linear inequalities.[1] Dantzig's method gives, to an

Vol. 7
Pt. 1
1956

extreme degree of accuracy, answers which have other quite useful properties; but the large number of computations involved (about $5m^3$ multiplications) entails round-off problems, and makes the solving of a reasonably sized program ($m=50$) a matter of several hours. Moreover, a change in the given data usually requires a rerun of the whole problem.

The analogue method will be especially useful in removing this last difficulty. In many practical problems the data are known with so little accuracy (much less than that of the values of the electrical components representing them) that it is important to be able to explore the solutions of a whole class of problems with data near those of the given problem. Since the author's method allows these changes to be made and solutions to be found quickly and examined for "reasonableness," uncertainty regarding data should no longer present as great an obstacle as heretofore in the application of linear programming to realistic problems. Moreover, certain nonlinear programming problems can be phrased as linear problems with variable coefficients, so that analogue methods may be useful here, too.

It seems difficult to formulate a precise general statement about the length of time required to obtain a solution by this method, but certain practical bounds on the rate of travel of the point x to the solution can be indicated.

Denoting by K the speed of x when no constraints are in play, suppose that x is constrained to move at an angle θ to its unconstrained direction. It is easy to see that the effect of the constraints will cause x to move with the speed $K \cos \theta$ in its new direction, so that the component of its velocity in the direction of the gradient is further reduced to $K \cos^2 \theta$.

In the worst case, x will travel along the 1-dimensional intersection of $n-1$ hyperplanes. We can obtain an average estimate of its velocity by finding the expected value of $K \cos^2 \theta$ for a line selected at random in n-space. The calculation is straightforward and yields the expected value

$$\overline{K \cos^2 \theta}=\frac{\int K \cos^2 \theta dS}{\int dS}=\frac{K}{n}$$

the integration being performed over the surface of the unit sphere in n-space. Although this number is small when n is large, few problems may be expected in which the solution would be very slowly approached, because this case will occur only toward the end of the problem and, in any event K can be made quite large.

Reference

1. Activity Analysis of Production and Allocation (book), edited by Tjalling C. Koopmans. John Wiley & Sons, Inc., New York, N. Y., 1951, pp. 339–47.

Insley B. Pyne: Dr. Wolfe's calculation for the order of magnitude of the speed of the objective point in n-space is interesting and, in my opinion, optimistic. The optimism arises from the assumption that the speed of the point along a single constraint is proportional to the cosine of the angle between the directions of constrained and unconstrained motion. Actually, the motion involves a saw-toothed path back and forth through the constraint so that the resulting component of the velocity along the constraint is smaller than Dr. Wolfe's estimate. As the vector field normal to the hyperplane is increased in magnitude, the return velocity increases and the constrained speed approaches Dr. Wolfe's value as a limit. Circuitwise, this corresponds to increasing the battery voltage E and/or multiplying the resistances r_{ji} to the inputs of the integrators by a factor less than one. Experiment shows, however, that there are limits to what can be done accurately by these methods.

MAGNETIC fields are used extensively in practice to help control the position or motion of an electric arc. Properly applied, they can be used as an aid to either the stabilization or extinction of an arc. Improperly controlled, they may introduce unwanted instability to an arc.

In spite of the wide application of magnetic fields to electric arcs, however, only meager knowledge of the fundamental behavior and mechanism of the motion of an arc in a magnetic field is available. Stolt[1] studied the rotation of an arc in a magnetic field but his work was limited to low-current arcs under 10 amperes. More recently, a number of investigations have been made of the motion of a low-pressure arc in a magnetic field in an effort to explain the retrograde motion of the arc.[2] Conclusions based on these results cannot safely be extrapolated to apply to high-pressure high-current arcs encountered in switchgear and arc welding.

This paper describes the behavior of d-c arcs at atmospheric pressure with currents up to 100 amperes when subjected to uniform magnetic fields up to 200 gauss. Electrodes studied include silver, copper, aluminum, carbon, tungsten, molybdenum, nickel, and titanium.

Experimental Procedure

The magnetic field was produced by a solenoid 3 feet in length by 12 inches in diameter. The solenoid was wound with 2,337 turns of wire in four layers on a form of glass-fiber cloth bound by Permafil.* End-turn correction was provided so that the field midway along the length was practically uniform throughout the cross section. The electrodes and contact-making mechanism were mounted on a textolite disk, 12 inches in diameter, which fitted snugly inside the solenoid.

The details of the electrode assembly are shown in Fig. 1. The electrodes were square rods 1/4 inch by 1/4 inch mounted parallel to each other along the diameter of the disk. The gap which could be adjusted by means of mounting screws was normally set at 1/8 inch. For copper and carbon electrodes, 1/4-inch commercial bars were used. Electrodes of other materials were brazed directly to the copper bars. The titanium strips were attached with the help of the General Electric Research Laboratory through the courtesy of Dr. Cobine. With the exception of carbon, all electrodes were polished either mechanically (copper, silver, nickel, aluminum) or electrically (tungsten and molybdenum). In general, the electrodes were mounted with their flat surfaces parallel. The edge mounting shown in Fig. 1 was an exception used during some of the preliminary tests.

Paper 56-132, recommended by the AIEE Committee on Basic Sciences and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted May 16, 1955; made available for printing November 21, 1955.

L. P. Winsor is with Rensselaer Polytechnic Institute, Department of Electrical Engineering, Troy, N. Y., and T. H. Lee is with the General Electric Company, Schenectady, N. Y.

This paper is based on the experimental part of a doctor's thesis presented by Mr. Lee to Rensselaer Polytechnic Institute, May 1954.

The authors wish to express their appreciation to J. W. Cooke, H. B. Rhoads, and T. K. Knapp, General Electric Company, for their support of this investigation; to J. H. Steadwell for his assistance in designing the test facilities; to J. H. Connery for his assistance with the photographic work; and to Dr. J. D. Cobine for assistance in procuring electrode materials.

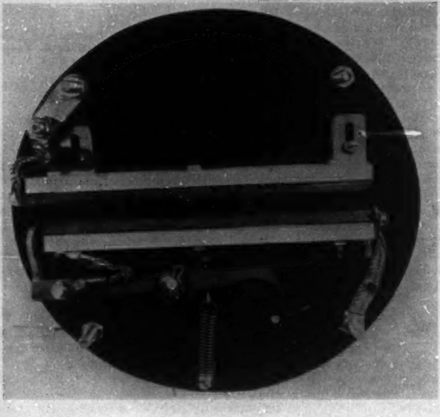

Fig. 1. Electrodes and arc-initiating mechanism

The circuit polarity was fixed so that the upper electrode was the cathode and the lower one the anode. A movable contact, connected electrically to the anode, made initial contact with the upper electrode and established the current. A cam, driven by a small synchronous motor mounted external to the solenoid, caused the movable electrode to separate from the fixed electrode to initiate the arc. The direction of the magnetic field was chosen so as to force the arc to transfer to the stationary anode and travel from left to right along the gap. The arc current was stabilized by an inductance of 40 millihenrys.

The arc was photographed periodically during transit by a still camera through the use of a simple, although effective, high-speed shutter. The shutter consisted of a revolving disk which was completely opaque except for ten transparent uniformly spaced half-degree sectors. It was made by placing a mask to duplicate the slits over a piece of photographic film and overexposing the remainder of the film. Such a shutter was very light and well balanced and posed no problems of balancing, even when turning at relatively high speeds. It was driven by an adjustable-speed d-c motor controlled by a Thymotrol drive. Fig. 2 shows a series of photographs recorded by the camera as the arc traversed the length of the electrodes. The film was subjected to a double exposure in order to include the contact assembly to orient the arc. Knowing the dimensions of the electrodes, the speed of the disk, and the spacing between slits, the distance and time between successive images could be measured and the velocity of the arc also could be calculated.

The arc voltage was recorded by a DuMont type *304A* cathode-ray oscillograph as indicated in Fig. 3. A 60-cycle 100-volt (peak-to-peak) square wave provided both a voltage and time calibration. The negative peak was adjusted so as to be coincident with the zero axis of the arc voltage. A special triggering circuit was designed and built to trigger the sweep at the instant the arc transferred from the movable to the fixed lower electrode.

Experimental Results

ARC TRAVEL

Two distinct modes of arc travel were observed. The first mode, which occurred in the lower current range, was distinguished by a cathode spot which moved continuously at a uniform velocity. The cathode spot left a continuous track, showing very little burning on the surface of the electrode. The appearance was similar to that described by previous authors for a "cold-cathode" arc.[3]

At the smallest currents, the anode spot, as well as the cathode spot, moved continuously, and the entire arc progressed along the length of the gap at a uniform velocity. Fig. 2 shows several exposures of such an arc between copper electrodes at a current of 3 amperes and flux density of 96 gauss. Because of the finite size of the slots, the shutter could not completely stop the motion so that the apparent width of the arc is somewhat greater than the true width. The arc voltage exhibited the usual random variation characteristic of the d-c arc. As might be expected, the average voltage was higher for the moving arc than for a comparable stationary arc.

When the arc current was increased to higher values, the anode spot no longer followed the uniform motion of the column, but tended to lag behind it and advance in discrete steps. Fig. 4 shows an arc between copper electrodes at a gap spacing of approximately 1/2 inch. The arc current was 71 amperes and the flux density 26 gauss. The series of photographs illustrates the manner in which the cathode and column advance under the influence of the magnetic field while the anode spot tends to lag. The formation of the new anode spots and extinction of the old ones is clearly exhibited. Apparently as the arc stretches out, the leading edge of the column is attracted toward the anode and comes close enough to the electrode to establish a new anode spot. It is not clear whether the column actually makes contact with the electrode or whether the voltage gradient simply reaches the necessary value to cause breakdown. When the new anode spot is formed, the arc tends to follow the shorter path and the previous anode spot is extinguished. During the transient period, however, multiple anode spots are often observed. The figure includes one exposure in which three such spots are in existence simultaneously.

The presence of discrete anode spots is further verified by the appearance of tracks observed on the electrode following the passage of the arc. The continuous track previously described has been replaced by a series of discrete, discontinuous spots separated by distances comparable to the spacings of the anode spots shown photographically. As might be expected from the manner in which the new anode spots are thought to be established, the separation between successive anode spots increases in general with an increase in the gap separation. The intermittent motion of the anode spot introduces a pronounced saw-tooth characteristic to the wave form of the arc voltage. Fig. 3 is a typical oscillogram, taken at a current of 12 amperes in a field strength of 29 gauss. It will be observed that the arc voltage apparently increases with time as the arc stretches out and then suddenly decreases when the formation of a new spot shortens the path.

Fig. 5 shows a family of curves of arc velocity as a function of flux density for copper electrodes with a gap spacing of 1/8 inch over a current range between 3 and 109 amperes. Owing to the fre-

Fig. 2. Photograph of a copper arc, double exposed to show electrodes; current 3 amperes, flux density 96 gauss

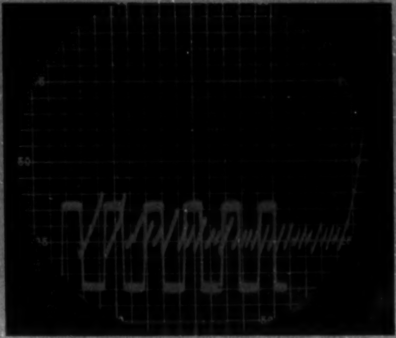

Fig. 3. Arc voltage across a copper arc; current 12 amperes, flux density 29 gauss; square-wave calibration 100 volts peak to peak, 60 cycles

quent failure of the photographs to reveal a distinct boundary to the column and to the intermittent motion of the anode spot over most of the range of the data, the velocity of the cathode spot was taken as the criterion for arc velocity. The shutter speed was so chosen that images were produced on the photograph at about 1/2-inch spacings, and the distance between spots could be measured to the nearest 1/64 inch, permitting a maximum error of measurement of the order of 3 per cent (%). The points plotted represent the average of several such velocities measured along the path of travel. In general the data follow smooth curves and are readily reproducible. The velocity along the path of travel was relatively constant for any one passage of the arc. In some measurements for copper the maximum deviation was as low as 2% of the average value while in the worst case, the maximum deviation reached 18%. With tungsten electrodes, a maximum deviation of 33% was measured.

The arc velocity was found to increase with an increase in either the arc current or flux density, and to be relatively independent of the cathode material, so long as the cathode spot advanced freely. Typical results are plotted in Figs. 5 and 6. However, when the arc current is increased beyond some critical value, dependent on both the flux density and the cathode material, the cathode spot ceases to advance with uniform motion. Rather, it tends to become fixed to one spot while the column is forced ahead by the magnetic field. When the column stretches out far enough, it may come into proximity with the negative electrode and help establish a new cathode spot. In this manner, the cathode spot tends to become oriented in discrete spots and to advance in a series of intermittent discontinuous steps. With this second mode of motion, both the cathode and the anode spots jump ahead randomly and apparently independently of each other, so that either spot may lead or lag the other, although both lag the column. The average velocity is reduced to a fraction of the velocity observed in the first mode.

The motion of the arc in the second mode of travel is illustrated by Fig. 7. The arc is between carbon electrodes at a current of 30 amperes in a magnetic field of 50 gauss. In the last four exposures of the arc, the cathode spot remained fixed in position while the anode spot continued to advance. In the first of the four exposures, the cathode spot (upper electrode) had jumped ahead of the anode spot which appeared to be in essentially the same spot as in the previous exposure. In the next exposure, the anode spot had jumped ahead of the cathode spot. In the third exposure, the anode spot had again jumped ahead while in the last exposure it had made little more progress. The failure of the cathode spot to advance further caused the arc to stretch itself out until it was extinguished. From the evidence of this illustration, it would appear that the arc column was blowing out toward the observer rather than along the electrodes so that ionization from the column could not help to establish a new cathode spot. Hence the arc was blown out before completing its travel along the electrodes.

Results for the second mode of travel are not reproducible as in the first mode, and quantitative data are limited. The arc voltage fluctuates between wide limits as both the cathode and anode spots move intermittently, and often reaches a high value when the cathode spot lags excessively. When the arc voltage reaches the open-circuit value without a new cathode spot being formed, the arc is extinguished. Sometimes the arc travels the entire length of the gap by establishing sucessive new cathode spots; other times it is extinguished in transit as demonstrated in Fig. 7. The conclusions

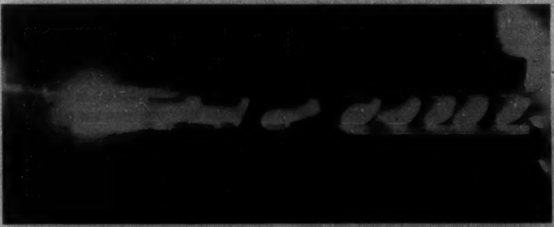

Fig. 4. Photograph of a copper arc, with top electrode cathode, bottom electrode anode; current 71 amperes, flux density 26 gauss

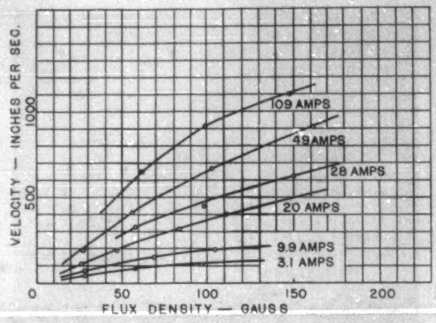

Fig. 5. Arc velocity versus flux density, copper electrodes, 1/8-inch gap

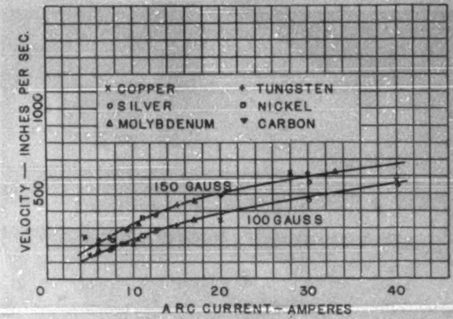

Fig. 6. Arc velocity versus current, 1/8-inch gap

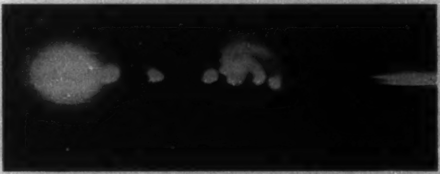

Fig. 7. Photograph of a carbon arc with top electrode cathode, bottom electrode anode, current 30 amperes, flux density 50 gauss

drawn from the photographs and oscillograms are correlated by the appearance of the cathode following arcing. The continuous tracks observed in the first mode have been replaced by discrete spots corresponding to the discontinuous cathode spots. In some cases these spots extend the length of the gap while in others they disappear part way along, verifying the incomplete passage of the arc.

The two different modes of arc travel were observed for most of the electrode materials studied. The current at which the transition was first observed was highest for copper, followed by silver. For the other materials tested, it was relatively low. The transition current increased with an increase in field strength as might be anticipated. A summary of transition currents and corresponding flux densities for a number of electrode materials has been tabulated in Table I.

Table I. Parameters for Transition in Arc Velocity

Electrode Material	Current, Amperes	Flux Density 1st Mode (High-Velocity), Gauss	 2d Mode (Low-Velocity), Gauss
Copper	109	62	25.8
	49	25.8	
Silver	55.5	100	68.8
	30	68.8	34
Tungsten	15	85	34
Molybdenum	33	155	120
Titanium	6		140
Carbon	30		155
	15	200	130
Nickel	22.5	172	172

For copper, the transition was first observed at a current of 109 amperes and a flux density of 25.8 gauss. The arc velocity was reduced to only 130 inches per second compared with about 300 inches per second predicted by extrapolating the data of Fig. 5 for an arc traveling in the first mode. A decrease in arc current to 49 amperes caused the arc to travel in the first mode again with the velocity increased to 200 inches per second. The second mode was not observed at this value of current. At 109 amperes, an increase in flux density to 62 gauss also caused the arc to revert to the first mode, increasing the arc velocity to 650 inches per second. With silver electrodes, the first mode was observed at 100 gauss for a current of 55.5 amperes, but the second mode occurred for the same current at 68.8 gauss. When the current was reduced to 30 amperes, the first mode again obtained at 68.8 gauss, but the arc reverted to the second mode again when the flux density was reduced to 34 gauss. For titanium the motion seemed to be in the second mode at currents as low as 6 amperes at a flux density as high as 140 gauss. Results for titanium were not reproducible. The second mode was observed for carbon at 30 amperes and a flux density as high as 155 gauss. When the arc current was reduced to 15 amperes, the first mode was found at a flux density of 200 gauss, but was replaced by the second mode at 130 gauss.

The transition point for nickel was found to be at a current of 22.5 amperes and a flux density of 172 gauss. Under these conditions both modes of motion were observed. When the motion was in the first mode, an arc velocity as high as 710 inches per second was measured. This speed was reduced to as low as 38 inches per second when the arc traveled in the second mode, a reduction ratio of nearly 19. Results could not be obtained with aluminum because the aluminum cathode burned easily and caused the cathode to pit, causing the column to stretch out until the arc was extinguished. This difficulty is reminiscent of experiments described by Cobine and Gallagher[4] in which the cathode spot demonstrated reluctance at crossing even a small scratch on the cathode surface.

ANODE CURRENT DENSITY

Until recently very little attention has been paid to the phenomena associated with the anode of a high-pressure high-current arc. Finkelnburg[5] has reported the high anode current density of the carbon arc and Kouwenhoven and Jones have reported the high anode current density observed in their study of an arc with a moving anode.[6] Cobine and Burger emphasized the importance of the anode region in a paper before the 1953 Gaseous Electronics Conference. A study of the tracks left by the anode of an arc moving in a magnetic field provides an excellent opportunity to estimate the current density of the anode spot. The technique employed was the same as that used by Cobine and Gallagher to measure the cathode spot current density.

A 1/2-inch gap was used during the study of the anode current density. This increased the separation between successive anode spots and helped distinguish between single and multiple spots. The tracks were observed to consist of small shiny centers surrounded by somewhat larger zones which appeared to be oxidized by the heat. The bright spots were assumed to be the anode spots. In general, they could be approximated by either circles or ellipses for the purpose of computing the area. Measurements were made for arc currents in the range between 50 and 75 amperes driven by fields of the order of 150 to 200 gauss. The anode current density was calculated as the ratio of the arc current to the area of the shiny part of the anode spot. A summary of the maximum and minimum values of the anode current density for a number of anode materials is given in Table II.

Table II. Anode Current Density

Anode Material	Anode Current Density, Amps per Sq. Cm. Maximum	Minimum
Nickel	16,000	10,000
Aluminum	36,000	17,000
Copper	44,000	26,000
Silver	44,000	28,000
Tungsten	66,000	40,000
Titanium	89,000	54,000
Molybdenum	110,000	51,000

The results show remarkable agreement with the approximation of 10,000 to 50,000 amperes per square centimeter estimated by Cobine and Burger. The higher current density measured for the highly refractory materials suggests that the anode temperature may be higher for refractory than for nonrefractory materials.

Discussion of Results

The results suggest the possibility of four types of motion for the d-c arc in a magnetic field:

1. Continuous motion of both the cathode and anode spots.
2. Continuous motion of the cathode spot and intermittent motion of the anode spot.
3. Continuous motion of the anode spot and intermittent motion of the cathode spot.
4. Intermittent or discontinuous motion of both the cathode and anode spots.

Of the four possibilities, the third was never experienced. In every case observed the motion of the anode spot became discontinuous at a lower current than the cathode spot. This is reasonable because the higher temperature normally associated with the anode would be expected to stabilize the position of the anode spot at a lower current than the cathode spot.

Continuous motion of both the anode and cathode spots was limited to low currents and high field strengths. The intermittent motion of the anode spot was observed at currents of only a few amperes and was characteristic of most of the arcs studied. No discontinuity was discovered in the magnitude of the arc velocity when the anode spot ceased to move continuously. This justifies the grouping of all arcs with a continuously moving cathode in the same mode of motion. The decreasing slopes of the curves for arc velocity as the current or flux density is increased, as illustrated by Figs. 5 and 6, suggest however that the discontinuous motion of the anode spot introduces a retarding force on the arc. The values of arc velocity for copper, silver, molybdenum, tungsten, nickel, and carbon were all found to follow the same curves, as demonstrated by Fig. 6, suggesting the conclusion that the arc velocity may be independent of the electrode material so long as the arc follows the first mode of motion. Stolt's conclusion that the arc velocity was independent of the cathode material suggests that his results were all obtained for arcs traveling in the first mode of motion. Quite likely, if he had increased the current with carbon electrodes, he would have experienced the effect of the second mode of motion on the arc velocity.

The discontinuous motion of the anode spot shows striking similarity to the motion of the anode spot of an arc between a fixed cathode and a moving anode, as observed by Kouwenhoven and Jones.[6] In their work, performed in the absence of a magnetic field, the anode spot tended to become fixed to the workpiece (anode) and was carried along, stretching out the column in much the same way as observed in this study, until a new spot was established on the workpiece opposite the cathode. In the present study, the anode spot again tended to hang onto the same spot on the anode surface while the magnetic field forced the cathode spot and column ahead. The general appearance of the column and the mechanism of establishing new anode spots appear to be similar in the two cases.

High peaks were left by the anode spots, similar to those described by Kouwenhoven and Jones. The peaks were highest with copper and relatively less pronounced for refractory materials. At low currents and high magnetic fields, the anode sometimes exhibited a continuous track or a track broken at a few spots. The formation of the peak is believed to be independent of the motion of the anode since a similar peak has been observed on the silver anode of an a-c contactor following arc extinction without the aid of a blowout coil. Alternating current was used and the arc current was interrupted at the normal current zero. The contact area was small and no evidence of motion of the anode spot was observed.

The discovery of the second mode of motion for the cathode is of basic significance to both the fundamental scientist and the design engineer. To the one, it adds to the knowledge of the fundamental behavior of the electric arc; to the other, it places a limitation on the amount of arc current that can be driven by a magnetic field. The transition in effect places a ceiling on the curent that can be driven at high speed in a reproducible manner. The ceiling can in general be kept at a maximum by the choice of a nonrefractory cathode and raised by an increase in the field strength. The transition current at which the cathode spot ceases to move continuously appears to be determined by the cathode material only. Measurements made with a copper or silver cathode and a refractory anode produced arc velocities in the first mode of motion for arc currents well above the transition values for cathodes of the same material as the anode. In this way, anode current densities (Table II) were measured with the arc traveling in the first mode for all the anode materials at currents far above the transition values that would have been encountered had both electrodes been of the same composition.

A new cathode spot is much more difficult to establish than a new anode spot so that reproducible results could not be obtained for the second mode of motion. With a clean electrode, the cathode spot tended to stick even at a low current and high field and irregular results were experienced for the first few passages of the arc with all electrode materials. Even for copper and silver cathodes, the cathode and anode spot both tended to stick during the first few operations and then the cathode spot began to move with discontinuous motion. Sometimes the cathode spot would move part way along the gap and then become extinguished. After several operations in this mode, the first mode would appear and would be the normal mode. When the cathode was highly oxidized at the start, the motion would initially be in the first mode. The need for an oxidized cathode has been recognized many times as essential to the establishment or maintenance of a cathode spot.

In most of the tests, the magnetic field was excited before the arc was initiated. When the arc was established first, the cathode tended to establish a hot spot before the arc started to move and the cathode would stick as if it were in the second mode. If the arc current and flux density were in the range that would normally permit motion in the first mode, however, the arc would start to move in the first mode as soon as a new cathode spot was formed. Even when the magnetic field was excited first, considerable delay occurred between the initiation of the arc and the start of the motion. This time, referred to as "sticking time" in contactor applications, was often several times greater than that which was required for the complete passage of the arc along the gap.

Discussion

C. G. Smith (Raytheon Manufacturing Company, Newton, Mass.): The magnetic field transverse to the arc current forces the air to one side in a blast that can be observed by suitably arranged vanes. The blast is in the expected direction and is probably the main factor causing the arc motion. However, there is another factor at work tending to move the arc in the opposite direction. This is revealed if one minimizes the air blast.

The electromagnetic force at given field strength is proportioned to the arc length times the arc current. The viscous drag on the air is inversely proportioned to arc length or spacing between terminals. Closer spacing of the terminals reduces the impelling force and increases the retarding force, thus minimizing the air blast. Some years ago I observed a copper arc between terminals about 0.030 inch apart at a variable pressure in the region of 10 centimeters of Hg. At the low pressures and with close spacing, the arc motion was retrograde (opposite to the expected direction). The vanes for detecting the blast of air always moved in the proper or expected direction. The vanes therefore moved contrary to the observed arc motion when the arc was proceeding in the retrograde direction.

It would be of interest if the observations could be repeated or extended by employing terminals whose spacing could be made quite small, the gas pressure being under control. The phenomena are conceivably of practical interest in deion circuit breakers or the like employed at high elevations with attendant reduced pressure. Furthermore the basic problem of arc motion in a transverse field is of scientific interest because we seem not to understand the retrograde motion; and we probably do not understand the sticking to a localized anode or cathode region as observed.

L. P. Winsor: The authors appreciate learning of Dr. Smith's observations concerning the retrograde motion of the arc in a magnetic field at low pressures. Their own experiments were conducted at atmospheric pressure and with a somewhat longer gap, so that the retrograde motion was not in evidence. However, there is no doubt that an extension of the work to lower pressures might lead to useful results both from a theoretical and from a practical viewpoint.

Magnetic Effects of Compressional Stress at Low Field Intensities

R. E. FISCHELL
ASSOCIATE MEMBER AIEE

Synopsis: Toroidal, laminated cores of several important magnetic materials were tested for the low-field-intensity magnetic properties at compressional stresses ranging from 0 to 500 pounds per square inch (psi). The compressional stress was applied in a direction perpendicular to the plane of the laminations and perpendicular to the direction of the magnetic field, thereby simulating the binding of magnetic laminations in transformers, electric motors, servo components, etc. The materials tested were hydrogen-annealed specimens of 3.5 per cent (%) and 6.4% silicon-iron, 81% and 90% nickel-iron, *4-79* and *5-79* molypermalloy, and hydrogen- and air-annealed specimens of *AEM-4750*, *12* Alfenol, and *16* Alfenol.

Two types of tests were made. The first test determined the effect of compressional stress on the d-c permeability for a range of magnetic field intensities from 0.1 to 100 milliorsteds. The second test determined the effect of compressional stress on the 60-cycle per second (cps) a-c magnetization curve for a range of peak magnetizing fields from 0.01 to 100 milliorsteds. Under the action of an increasing compressional stress, each of the materials tested exhibited a decrease in low field permeability and an a-c magnetization curve that was shifted downward. The degree to which the permeability and a-c flux density changed with increasing compressional stress varied widely from one material to another, but for each material the d-c permeability and a-c flux density decreased by approximately the same percentage of the zero pressure measurement of these quantities.

MAGNETIC materials are very frequently used in the form of a clamped stack of laminations. For this configuration the direction of the clamping stress is perpendicular to the plane of the laminations and perpendicular to the direction of the applied magnetic field. It is therefore of interest to observe the

effect of this transverse compressional stress on the magnetic properties of laminations.

A previous paper[1] discusses the effect of transverse compressional stress on the a-c hysteresis loop and magnetization curve, and on the maximum permeability, coercive force, remanence, and saturation flux density of several important magnetics materials. The purpose of this paper is to describe the effect of transverse compressional stress on the a-c and d-c magnetic properties at very low magnetic field intensities.

The materials tested were hydrogen-annealed specimens of 3.5% and 6.4% silicon-iron, 81% and 90% nickel-iron, *4-79* and *5-79* moly-permalloy, and hydrogen- and air-annealed specimens of *AEM-4750*, *12* Alfenol, and *16* Alfenol. The specimens tested were laminated toroids with thin-paper insulation between the laminations. The toroids measured 1⁵/₈-inch inside diameter and 2.0-inch outside diameter; the lamination and insulating paper thicknesses measured 0.015 and 0.001 inch respectively.

Experimental Procedure

The compressional stress was applied by placing the laminations in a special fixture, shown in Fig. 1. With the use of this device, a compressional stress of varying magnitude was exerted on the sample without interfering with the electrical windings which are necessary for the determination of magnetic properties.

The device for applying the compressional force was a lever and scale system, shown in Fig. 2. With this system it was possible to maintain constant pressure on the sample while it was being tested, and it was also possible to increase the compressional stress in increments of 100 psi without relieving the stress while changing from one pressure to another.

Two types of tests were made, and for each test the magnetic properties were measured at compressional stresses of 0, 100, 200, 300, 400, and 500 psi, and the low field properties were also measured after the stress had been removed. The first of these tests was the measurement of maximum a-c flux density at a frequency of 60 cps with peak magnetizing fields ranging from 0.01 to 100 millioersteds. The second test was the measurement of d-c permeability at magnetic fields ranging from 0.1 to 100 millioersteds.

The circuit for the a-c measurements is shown in Fig. 3. The magnetizing current was controlled by means of a Variac and a variable-coupling air-core mutual inductor. With this arrange-

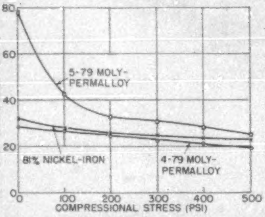

Fig. 8. D-c permeability as a function of compressional stress for 81% nickel-iron, 4-79 and 5-79 moly-permalloy

ment it was possible to obtain and control the very low voltages which were necessary to produce the extremely small magnetizing currents required for the a-c measurements. In terms of the peak-to-peak voltage measured across the primary current metering resistance R_H, the peak magnetizing field is given by the relation

$$H_m=\frac{0.2\pi N_1}{L_m R_H}V_{p-p} \text{ oersteds} \tag{1}$$

where

N_1 = number of primary turns
R_H = metering resistance in ohms
L_m = mean length of the toroid in centimeters
V_{p-p} = peak-to-peak voltage in volts

In the a-c experiments, 32 evenly spaced turns were used for the primary winding, and with the use of a metering resistance of 139.0 ohms the relation between the peak-to-peak voltage and the magnetizing field takes the simple form

$$H_m=10V_{p-p} \text{ millioersteds} \tag{2}$$

To measure the peak a-c flux density produced at a very small value of H_m it was necessary to use a low-level preamplifier in conjunction with a sensitive electronic vacuum tube voltmeter of the rectified average-reading type. With the circuit shown in Fig. 3, the combined noise level of the preamplifier and voltmeter was equivalent to an input signal of less than 2.5 microvolts. This noise level was considerably below the lowest signal measured in the a-c tests.

In terms of the readings of a rectified average-reading voltmeter the maximum a-c flux density is given by

$$B_m=\frac{V_{2_{\text{rms}}}\times 10^8}{\pi\sqrt{2}mN_2Af} \text{ gauss} \tag{3}$$

where

$V_{2_{\text{rms}}}$ = voltage as measured by a rectified average-reading voltmeter calibrated in rms voltage of a sine wave
m = gain of the preamplifier
N_2 = number of secondary turns
A = cross-sectional area of the toroid in square centimeters
f = frequency in cps

The initial permeability can be determined from a-c measurements with the use of the relation

$$\mu_0=\lim_{H_m\to 0}\frac{B_m}{H_m} \tag{4}$$

$$\mu_0=\lim_{H_m\to 0}\frac{L_m R_H V_{2_{\text{rms}}}\times 10^8}{0.2\sqrt{2}\pi^2 mN_1N_2AfV_{p-p}} \tag{5}$$

The second test used the standard d-c fluxmeter circuit to determine the permeability at low values of magnetic field. For the d-c case, the magnetizing field is given by the familiar toroid equation

$$H=\frac{0.4\pi N_1 I_1}{L_m} \text{ oersted} \tag{6}$$

where I_1 = primary current in amperes.

The flux density can be found from the relation

$$B=\frac{K}{2N_2A}d \text{ gauss} \tag{7}$$

where

K = fluxmeter constant in maxwell-turns per centimeter
N_2 = number of secondary turns
d = fluxmeter deflection in centimeters

The permeability will then be given by

$$\mu=\frac{B}{H}=\frac{L_mKd}{0.8\pi N_1N_2AI_1} \tag{8}$$

and the initial permeability is given by

$$\mu_0=\lim_{H\to 0}\frac{L_mKd}{0.8\pi N_1N_2AI_1} \tag{9}$$

The value of the initial permeability obtained from equation 5 with a-c measurements should be equivalent to the value obtained in equation 9 with d-c data.

Magnetic measurements at extremely low field levels require precautions which can usually be neglected when most magnetic properties are measured. Three important factors which had to be considered in the performance of these low-field experiments will be discussed briefly.

1. The effect of an external field large compared to the impressed magnetizing field.
2. Demagnetization of the specimens.
3. Means of eliminating or minimizing electromagnetic pickup.

Since measurements were made at fields of less than 1/10,000 that of the earth's field, it was necessary to determine if a comparatively large external field can cause errors in the measurement of flux density. To determine the effect of a comparatively large external field, the low-level flux density was measured at three different magnitudes of external field: 1. less than 10^{-5} oersteds, 2. the earth's field, and 3. double the earth's field. The results of these experiments were negative, i.e., the apparent flux density of the toroid was unaffected by external fields of these magnitudes. It was therefore decided that the experiments could be accurately performed without shielding the toroids from the earth's magnetic field.

When demagnetizing to very low flux levels it is important to use a smoothly decreasing magnetic current such as that produced by a variable-coupling mutual inductor. The small but discrete voltage steps produced by turning down a device such as a Variac can sometimes cause the material to be left in an undemagnetized condition.

For the a-c measurements, stray electromagnetic pickup must be minimized by grounding the system to a quiet ground, as shown in Fig. 3, and by minimizing the resistance of the secondary winding.

Experimental Results

Some typical results of the effect of compressional stress on low-field a-c magnetic properties are shown in Figs. 4, 5, and 6. Fig. 4 shows the effect of exerting a compressional stress of 500 psi on the a-c flux density of hydrogen-annealed specimens of *12* Alfenol and 3.5% silicon-iron. It should be noted that these curves are straight lines for these extremely low field intensities, and it can therefore be assumed that the region of initial permeability is reached, as defined in equation 4. The compressional stress decreased the value of the initial permeability of all the materials that were tested. This decrease in initial permeability at higher values of stress is seen in Fig. 4 as a decrease in the slope of the straight-line magnetization curve.

Fig. 5 shows the effect of a 500-psi stress on two typical materials, air-annealed *16* Alfenol and hydrogen-annealed *AEM-4750*. The field intensities used for Fig. 5 are one order of magnitude greater than those shown in Fig. 4. From the nonlinear behavior at the ends of the magnetization curves shown in Fig. 5, we see that these materials are leaving their region of initial permeability. At these higher fields, the effect of the compressional stress was to shift the magnetization downward without an appreciable change in its shape.

Fig. 6 shows the effect of increasing the compressional stress while keeping the value of the peak magnetizing field constant at $H_m = 0.10$ millioersteds. The materials shown here are *4-79* and *5-79* moly-permalloy, 81% nickel-iron, and *AEM-4750*. These curves show that the *5-79* moly-permalloy had the highest value of initial permeability and also the greatest sensitivity to compressional stress.

The results of the a-c measurements on all the materials tested are shown in Table I. The numbers in the column headed O_R are the percentage change in B_m after the stress was removed. Most of the materials returned within a few per cent to their prestressed value of B_m.

Some typical results of the d-c measurements of low field permeability as a function of compressional stress are shown in Figs. 7 and 8. The d-c permeability as a function of field strength is plotted in Fig. 7 for the materials *5-79* moly-permalloy and 81% nickel-iron at compressional stresses of 0 and 500 psi. The higher stress decreased the permeability at all values of the magnetic field. This was true for all the materials tested. Fig. 8 shows the result of increasing the compressional stress on specimens of *4-79* and *5-79* moly-permalloy and 81% nickel-iron while holding the field intensity constant at $H = 1.0$ millioersted. These curves are strikingly similar in shape to the a-c flux density curves as a function of stress, as shown in Fig. 6.

The results of the d-c permeability measurements on all the materials tested are shown in Table II.

Conclusions

From the experimental results, the following conclusions regarding the effect of transverse compressional stress at low field intensities can be drawn:

1. Increasing the compressional stress causes the a-c magnetization curve to be shifted downward. At very low fields this is equivalent to a decrease in the initial permeability.

2. Increasing the compressional stress decreases the low field intensity d-c measurement of permeability.
3. The percentage change in magnetic properties varies widely from one material to another but, in general, materials with the highest initial permeability showed the greatest stress sensitivity.
4. At magnetic fields over one oersted the compressional stress sensitivity was found to be dependent on the magnitude of the magnetostrictive constant of the material.[1] At low fields, however, the variation of magnetic properties with compressional stress does not appear to have any correlation with magnetostriction.

Discussion

John Cybulski (Naval Research Laboratory, Washington, D. C.): Would the author comment on whether the effects of this stress may be explained qualitatively by considering that a normal compressive stress on an oblique plane can be resolved into a compressive and tangential (shearing) component? The maximum value of this shearing stress occurs on a plane making a 45-degree angle with the plane on which the normal stress occurs and is one-half that value. In general, the shearing strength is much less than the compressive or tensile strength so that it may be the more significant stress. This stress may then be along one of the various preferred axes of orientation of the ferromagnetic crystalline structure, e.g., the 111 direction where 001 is taken to be in the direction of rolling and the 110 direction is perpendicular to it and in the plane of the sheet.

The effects of simple tensile and compressive stresses in the direction of the field on the magnetic characteristics has been covered previously. However, Poisson's ratio relating the lateral dimensional change to the longitudinal change (about one-fourth for steel) may be also significant under transverse stresses.

It would be interesting to determine the effects of hydrostatic pressure on these materials to see if there would be a reinforcement of these shearing stresses.

The possible lack of correlation between the magnetostrictive properties and the effects of transverse compressional stress at low field intensities may be due only to the fact that at present there are insufficient data available on the magnetostriction constant at the low intensities studied. In the author's first paper (see reference 1 of the paper) there was some correlation which might be related to the shearing stresses discussed. Many materials, notably, the iron-silicon alloys, exhibit negative and positive magnetostrictive properties, depending on the field intensities supported by the core material.

R. E. Fischell: No material used for these experiments on transverse compressional stress was grain-oriented. Since these are polycrystalline materials having no preferred axis of orientation, there is no reason to believe that the observed decrease in magnetization is due merely to the presence of a shearing stress along an oblique plane. Although the lateral dimensions are changed according to Poisson's ratio, no qualitative explanation can be found here because this same strain was present for materials having both positive and negative magnetostriction, and yet each showed a decrease in magnetization with increasing stress.

Experiments now being performed at the Naval Ordnance Laboratory to determine the effect of hydrostatic pressure on magnetic materials may lead to a better understanding of the effect of transverse stress on magnetization. I agree that the phenomenon at low field intensities may have some correlation with magnetostriction, but at present there are no data known to the author on magnetostriction at magnetic field intensities below 1.0 millioersted.

A Digital Computer Program for Determining Atomic-Wave Functions

W. W. PIPER
NONMEMBER AIEE

SOLUTION of a set of second-order differential equations for computing Hartree-Fock self-consistent field wave functions has been successfully programmed for use on an International Business Machines Corporation (IBM) type *650* magnetic drum digital computer. These equations are nonhomogeneous and have coefficients which are functions of the solution. Thus, the equations must be integrated a sufficient number of times to reach a state of self-consistency. For a particular atomic configuration this may be accomplished in 5 to 8 hours of machine time with the present program. This represents a tremendous saving over hand methods previously used.

Accurate atomic-wave functions are of considerable use and importance in certain branches of solid-state physics. The exact wave functions are solutions of the Schrödinger equation, a differential equation which is basic to quantum mechanics. For 1-electron atomic systems, such as H (hydrogen), He^+ (helium), and Li^{+2} (lithium), the Schrödinger equation can be solved exactly and the resulting wave function can be written down in analytical form. If a system consists of two or more electrons, there no longer exists an analytic solution and an approximation must be sought. The Hartree-Fock equations yield wave functions which represent most accurately many of the properties of an atomic configuration. They were first conceived over 20 years ago by Hartree[1] and Fock.[2] These equations are a set of interconnected second-order differential equations which are restricted by certain boundary conditions as well as conditions of orthonormality. The excellence of these equations is handicapped by the lengthy and laborious numerical work that is required to arrive at a solution for a particular configuration. For this reason, only 24 or so computations have been carried through, by use of desk calculating machines in the past 20 years. Depending on the experience of the person carrying out the calculations, a few months to a year is required to determine a solution. With the advent of high-speed digital computers, these solutions can be determined in a few hours.

The fundamental investigation of luminescence processes serves as a good example of the type of work for which these atomic-wave functions are useful. Luminescent materials are commonly known as phosphors. Well known examples of phosphors are the luminescent components of cathode-ray tubes and fluorescent lamps. The spectral characteristics of emission and absorption of light by a phosphor are determined by the activator impurity incorporated in the phosphor. The activator material is atomically dispersed throughout the crystalline host lattice with a specific host lattice environment. An example is potassium chloride activated with thallium. A model of this system is shown in Fig. 1. Each thallium activator center is located at a potassium ion site and may be treated as surrounded by an infinite lattice of potassium chloride. This system has been treated theoretically from fundamental principles by Williams,[3] and is the first phosphor system to be so calculated. The calculated emission and absorption bands are in excellent agreement with experimental data. In order to calculate these spectra, the total energy of the lattice must be calculated with the thallium ion in the ground state and in the lowest excited state. In order to calculate some of the terms contributing to the energy of the lattice, it is necessary to know the radial charge distribution of the electron cloud surrounding the ion, that is, the charge density at a given radius from the nucleus. It is this information that can be best approximated by a Hartree-Fock calculation.

In the past, specific phosphor systems have been developed in an empirical manner. However, due to the pioneering work of Williams, and other recent advances in the understanding of the underlying physics of impurity systems in crystalline solids, the interpretation of phosphor phenomena is rapidly becoming intelligible from fundamental considerations. As the solid-state physics of a variety of phosphors becomes evident in increasing detail, the task of optimizing these and new phosphors for specific jobs will certainly become correspondingly simplified. An important link in such a program would be the ready availability of accurate atomic-wave functions such as the Hartree-Fock functions. The use of a digital computer such as a IBM *650* has now made it possible to compute several such wave functions in a reasonable length of time.

Numerical Procedure

The Hartree-Fock scheme consists mathematically of a finite set of second-order nonhomogeneous linear differential equations with coefficients which are integral functions of the solutions of all the equations. The solutions can be approximated to the accuracy of the difference equations by an iterative technique.

There is a wave function $P_\alpha(r)$ associated with each shell of electrons (electrons with the same principle and orbital angular momentum quantum number). For example, the ground state of Cu^+ (copper) has six shells so that there are six functions $P_\alpha(r)$ and also six interconnected differential equations. For an ion with n shells,

$$
\begin{aligned}
&\frac{d^2}{dr^2}P_1(r)+g_1(r)P_1(r)+f_1(r)=0\\
&\quad\cdots\cdots\\
&\frac{d^2}{dr^2}P_\alpha(r)+g_\alpha(r)P_\alpha(r)+f_\alpha(r)=0 \qquad (1)\\
&\quad\cdots\cdots\\
&\frac{d^2}{dr^2}P_n(r)+g_n(r)P_n(r)+f_n(r)=0
\end{aligned}
$$

$P_\alpha^2(r)dr$ represents the amount of charge contained in a volume between spheres of radius r and $(r+dr)$ due to one electron in the αth shell. Since $P_\alpha^2(r)$ describes the radial distribution of one electron in all space, this function must be normalized.

$$\int_0^\infty P_\alpha^2(r)dr=1 \qquad (2)$$

In addition, this function must be orthogonal to all the other wave functions P_α

Paper 56-155, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 20, 1955; made available for printing December 22, 1955.

W. W. PIPER is with the General Electric Company, Schenectady, N. Y.

The author expresses appreciation to Prof. D. R. Hartree for several invaluable discussions during the early stages of this work, and to Miss Mary Tressel and Miss Elise Krieger for their help in coding and correcting the program and for running the problem on the IBM *650*.

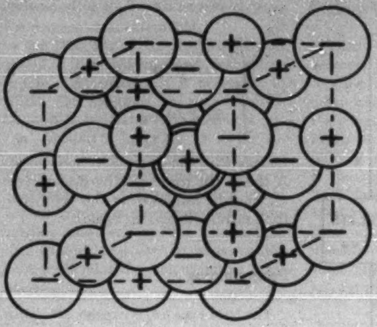

Fig. 1. KCl–Tl which is a representative example of an inorganic phosphor system. The ion at the center of the cube is a thallium ion substituted at a potassium ion site. The other positive spheres represent potassium ions and the negative ones chlorine

with the same orbital angular momentum, l,

$$\int_0^\infty P_\alpha P_\beta dr = \delta_{\alpha\beta},\ (l_\alpha = l_\beta) \tag{3}$$

and it must disappear at the boundaries $r = 0$ and $r = \infty$,

$$P_\alpha(0) = P_\alpha(\infty) = 0 \tag{4}$$

The functions g_α and f_α of equation 1 which are associated with the equation for a particular shell, depend on the wave function P_α and also on all the other wave functions. For this reason the solution P_α of each of the shells must in turn be repeated with better estimates of g_α and f_α until a state of self-consistency has been reached. That is, until a set of solutions of equation 1 agree with the functions that were used to compute the g_α's and f_α's. These coefficients are of the form

$$g_\alpha = \frac{\gamma_\alpha}{r} - \frac{L_\alpha}{r^2} - \epsilon_{\alpha\alpha} \tag{5}$$

$$f_\alpha = \frac{\phi_\alpha}{r} - \sum_\beta^{r}{}' \epsilon_{\alpha\beta} P_\beta \tag{6}$$

where

$$\gamma_\alpha = N - \sum_\nu b_\nu Y_{0\nu\nu} + \sum_i c_i Y_{n_i \alpha\alpha} \tag{7}$$

$$\phi_\alpha = \sum_k d_k Y_{n_k \alpha\beta_k} P_{\beta_k} \tag{8}$$

and

$$Y_{n\alpha\beta}(\rho) = \int_0^\rho P_\alpha(r) P_\beta(r) \left(\frac{r}{\rho}\right)^n dr + \int_0^\infty P_\alpha(r) P_\beta(r) \left(\frac{\rho}{r}\right)^{n+1} dr \tag{9}$$

Most of (γ_α/r) is the coulomb potential experienced by an electron in the αth shell, (L_α/r^2) is the effective potential due to the angular momentum of the αth shell, and $\epsilon_{\alpha\alpha}$ is related to the total energy of the αth shell. ϕ_α/r is an exchange potential which represents noncoulombic interactions between the shells. $\epsilon_{\alpha\beta}$ is adjusted so that the condition expressed in equation 3 may be satisfied. $\epsilon_{\alpha\alpha}$ is varied to satisfy conditions in equations 2 and 4. The other variable at one's disposal to help satisfy these two conditions is the slope of the function at the origin. There exist many solutions for P_α in equation 1 which satisfies the conditions of equations 2, 3, and 4. However, each solution has a different number of nodes, and the solution with the proper number of nodes may be chosen from quantum mechanical considerations.

Integration of the differential equation 1 and execution of the quadratures in equation 9 cannot be carried out analytically so that approximate solutions must be computed by numerical techniques. The most convenient schedule for many numerical procedures is to adopt a set of equally spaced points along the axis of the independent variable. For the problem discussed here, this arrangement is not suitable. Instead, the independent variable, r, is divided into groups of an even number of equally spaced intervals. The interval length changes by a factor of 2 between adjacent groups. This arrangement produces a minimum of complications that must be handled at a change of interval size. Fig. 2 illustrates the subscript convention used in the rest of this section. The value of r at the end of an interval is denoted by a subscript and the value of a function at that point by the same subscript. The subscripts increase by one with increasing values of r. The interval length is denoted by h. Thus,

$$r_{i+1} = r_i + h$$

$$f_\alpha(r_i) = f_i \tag{10}$$

Numerical quadratures are approximated by fitting a parabola through the three points associated with a pair of intervals and calculating the area under this parabola. This area may be expressed analytically and will be reduced to

$$\int_{r_i}^{r_{i+1}} f(r)dr = \frac{h}{12}(5f_i + 8f_{i+1} - f_{i+2}) \tag{11A}$$

$$\int_{r_{i+1}}^{r_{i+2}} f(r)dr = \frac{h}{12}(-f_i + 8f_{i+1} + 5f_{i+2}) \tag{11B}$$

These expressions have the advantage of not requiring any interpolation of values near the point where a change of interval size occurs. For an even number of intervals, equation 11 reduces to Simpson's rule. The error which is introduced by this approximation is approximately $(\delta^4 P/10)$.

The integration of any one of the equations in equation 1 subject to the boundary condition equations 2, 3, and 4, has been divided into three differential equations for machine computations according to a scheme suggested by Hartree in a private communication. Each equation is integrated by a difference equation technique which is discussed by Milne.[4] This difference equation can be used to obtain an approximate solution of a linear second-order differential equation at a set of equally spaced points. For an equation of the form of equation 1, the solution at r_{i+1} is given by

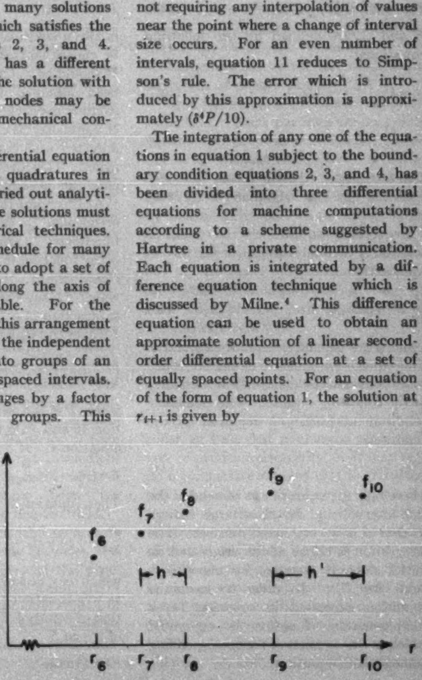

Fig. 2. Illustration of the subscript notation for a function, f(r), represented at a finite number of equi-spaced values of r. A change of interval size is also shown

Fig. 3. Block diagram of the steps involved in iterating one Hartree-Fock atomic-wave function

$$P_{i+1} = Z_{i+1}\left(1 + \frac{1}{12}\,h^2 g_i\right)^{-1} \tag{12A}$$

where

$$Z_{i+1} = (2 - G_i)Z_i - Z_{i-1} - F_i \tag{12B}$$

F and G are defined by the following equations:

$$G_i = h^2 g_i\left(1 + \frac{1}{12}\,h^2 g_i\right)^{-1} \tag{12C}$$

$$F_i = \frac{h^2}{12}\,(f_{i-1} + 10 f_i + f_{i+1}) \tag{12D}$$

The first neglected term of this difference equation has been shown to be (1/240) $\delta^6 P_i$.

In solving equation 1 in parts, a solution is first determined for the follow-equation:

$$\frac{d^2}{dr^2}P^+ + gP^+ + \phi = 0 \tag{13}$$

g and ϕ are defined in equations 5 and 8. This equation is made to fit the boundary conditions and the condition of normality in the following manner. The boundary condition at infinity is replaced by the condition

$$P(r_n) = a \tag{14}$$

where r_n is the value of r at the end of the last interval and is taken large enough so that a is a very small number. The integration is begun at the origin and an initial slope is assumed by choosing a value for P_1^+. In order to meet the condition expressed in equation 14, a complementary function is computed which is the solution of the corresponding homogeneous equation.

$$\frac{d^2}{dr^2}Q + gQ = 0 \tag{15}$$

The function

$$P = P^+ + xQ \tag{16}$$

is also a solution of equation 13. x may be chosen so that equation 14 is satisfied. It should be noted that a value of $\epsilon_{\alpha\alpha}$ has been assumed to calculate g. This solution is checked to see if the condition of normality is satisfied. If not, $\epsilon_{\alpha\alpha}$ is adjusted and equation 13 is integrated again. This cycle is repeated until the condition is satisfied.

At this point the solution must be made orthogonal to one or more other wave functions. In practice not more than one other function is involved to any appreciable extent. If P_β is the function to which P_α must be made orthogonal, then subtraction of equation 13 from equation 1 leaves the equation

$$\left(\frac{d^2}{dr^2} + g_\alpha\right)(P_\alpha - P) - \epsilon_{\alpha\beta}P_\beta = 0 \tag{17}$$

where P is the solution expressed in equation 16 and P_i is the solution required by equation 1. If S is defined as follows:

$$S = (P_\alpha - P)/\epsilon_{\alpha\beta} \tag{18}$$

Then equation 17 becomes

$$\frac{d^2}{dr^2}S + gS - P_\beta = 0 \tag{19}$$

which may be solved by the same program as was equation 13. Then the final solution of equation 1 is a linear combination of P and S.

$$P_\alpha = P - \epsilon_{\alpha\beta}S \tag{20}$$

$\epsilon_{\alpha\beta}$ is chosen so that P_α is orthogonal to P_β

$$\epsilon_{\alpha\beta} = \frac{\int_0^\infty P(r)P_\beta(r)\,dr}{\int_0^\infty S(r)P_\beta(r)\,dr} \tag{21}$$

Usually P_α is still very closely normalized. If this is not true, for a particular case, $\epsilon_{\alpha\alpha}$ must be readjusted at this point, and the equations integrated again.

Programming

The IBM type *650* is capable of storing 2,000 words on a magnetic drum memory. Sixty-four has been determined to be a sufficient number of values of r to yield an accurate solution with the difference equations which are used. With this many values of r it is possible to handle up to six shells of electrons without loading information into the machine in parts. Together with associated constants the input data require approximately 600 storage positions. Another 260 positions are needed to store intermediate results such as P^+ and g. Standard read and punch routines require about 100 positions. This leaves a little more than 1,000 words for the program. The present program uses almost all of this space.

A flow sheet is shown in Fig. 3 which indicates in block outline the steps taken to re-estimate the solution for one of the shells. The maximum value of any of the wave functions for any ion in the lighter end of the periodic table has well-defined limits which are separated considerably less than two orders of magnitude. For this reason, by careful planning of the sequence of the arithmetical steps, the whole program may be written in fixed point form.

At present the time required to complete one loop of the program requires from 15 to 25 minutes of machine time. By extrapolating from known solutions of other near-by ions it is usually possible to estimate starting functions closely enough (i.e., within a few per cent) to arrive at a self-consistent solution (within .01 or .02 per cent) after two or three iterations of each shell. The least tightly bound shell sometimes requires an additional one or two iterations. Thus the radial charge distribution of an ion with six shells of electrons may be obtained in approximately 5 hours of machine time. No attention has been given to optimizing the program by placing sequential orders that are used frequently in storage positions separated by an appropriate storage access time. This would shorten the running time severalfold.

The IBM *650* appears to be quite well suited to these self-consistent field calculations. At present it is necessary to watch the solutions as they progress through each iteration and exercise a certain amount of judgment as to the sequence of the iterations and the damping factor to be used in estimating the next trial solution. A faster machine would use an inordinate percentage of the time reading and writing this information. The IBM *650* uses 10 to 20 per cent of the time performing these input-output operations.

Conclusions

There is a need for readily available and accurate atomic-wave functions for theoretical studies of luminescent systems and other solid-state problems. The Hartree-Fock equations will produce good wave functions but are quite tedious to compute by hand methods. With a machine of intermediate speed and reasonably large fast-access memory, such as the IBM type *650*, it is possible to compute these wave functions in a few hours of machine time. A program to compute these functions is now operating so that any future needs for the wave functions of ions not yet computed can be made available in a short time.

Practical Applications of Electrostatic Phenomena to Particulate Matter

OLIVER C. RALSTON
NONMEMBER AIEE

THE behavior of particulate matter in electrostatic fields has been utilized in a number of industries; some are well known and others less known. A comprehensive picture cannot be put into one short paper, but several aspects of electrostatic technology deserve comparison and correlation. Those processes chosen for consideration in this paper are indicated in the headings.

Electrostatic Separation of Solid Particles

There are six or more electrostatic processes for separating mixtures of solid particles, but only the process using differences in conductance of the solids is widely known. All use an electrostatic field, commonly pulsating direct current, but sometimes alternating current, at high voltage, applied between two electrodes. In some instances the mixture falls in free air between the electrodes, and in some it travels into the field on a horizontal rotary cylinder or slides down a chute which acts as one of the electrodes, charged with respect to earth but usually grounded. Conductance separators utilize the difference in conductance of mineral particles, particles of high conductance acquiring a charge by contact with a charged conductor, or by being sprayed with a corona discharge. Frictional electric charging caused by rubbing of solid particles against each other, or against the feeder, or against the chute before reaching the electric separating field or while passing through it, is usable but less known. Differences in dielectric constant are utilized in other separators; see Fig. 1.

In Fig. 1, the field between electrodes is occupied by air or by a liquid of dielectric constant between two particles to be separated. Charged particles migrate toward oppositely charged electrodes, plus and minus. Dipoles migrate into the densest field. Particles of high dielectric constant compared to medium migrate toward the dense field; those of lower dielectric constant than the medium, away from the densest field.

Conductance electrostatic separators have been in use for nearly 50 years, and several firms sell machinery of this type. They operate by conveying a mixture of solid particles of markedly different conductance, such as metal sulfides (conductive) and silicates (poor conductors), into a zone where the charge can be fed to the conductive particles and simultaneously or shortly thereafter subjected to a static field of reasonably high intensity. Passage through the separating field takes place while the mixture of solid particles may be sliding down a chute or falling freely in air, or being conveyed over a charged or grounded roller, or carried on a belt. Charged particles of a definite sign are attracted toward the oppositely charged electrode that helps define the geometry of the field or is repelled by the electrode of the same sign of charge; see Fig. 2.

Fig. 2 (A) shows a model with a purely static field. Black particles are poor conductors and drop off the charged feeder electrode without deflection into the collecting bin *B*. Bin *A* is the feed bin. Particles of conductive minerals, denoted by hollow circles, take on the same charge as the carrier electrode and are repelled toward the other electrode to drop into bin *C*. In Fig. 2 (B) is shown a spray or corona discharge from a wire or knife edge pinning poor conductors to the carrier electrode.

Several dozen forms of apparatus merit attention. The means of getting electrostatic charge onto conductive solid particles is also quite variable. The mixture may rest on a conductive chute, roller, or belt that is charged with positive or negative electricity, or it may rest on a conductive support that is grounded but nevertheless has earth potential toward an insulated, highly charged electrode that forms the other boundary of the electric field. Only the good conductive particles receive effective charge in amounts to permit them to jump from their support, or be deflected from a falling trajectory by the presence of a highly charged electrode of opposite polarity. A corona or spray charge can

Paper 56-114, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 24, 1955; made available for printing December 7, 1955.

OLIVER C. RALSTON is with the U. S. Bureau of Mines, Washington, D. C.

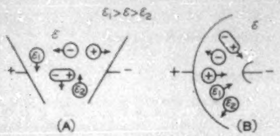

Fig. 1. Forces exerted in an electric field: horizontal section, looking down. Marked differences shown in field intensity of separators

be directed onto particles carried on conductive chutes, rollers, or belts; if the latter are grounded, the conductive particles at once lose their charge to ground, whereas the poor conductors cannot do this and they become electrostatically pinned to the carrier electrode.

If two different types of particles in a mixture differ markedly in dielectric constant they can be said to have different electron atmosphere pressures within them, and on rubbing together and then separating them it would be found that electrons have flowed from one type of particles to those of the other type. In common terms, frictional electricity has been created, with one set of particles positively charged and the other negatively charged. Dropping them through a static field will cause positive particles to deflect toward the negative electrode and negative particles toward the positive electrode, thus permitting a separation.

Particles that are essentially dipoles (charged oppositely at the two ends) before or while they are in a high-intensity field, tend to migrate from zones of low field intensity to those of high field intensity. This calls for apparatus wherein one electrode may be a plate of extensive area and the oppositely charged electrode may be one of very small area, such as a wire, around which field intensity is very high. The particles may be dropping vertically through such a field and the electrodes aligned in vertical position to allow deflection of the most pronounced dipoles to the zone of intense field.

Heating certain minerals, like quartz, causes pyroelectric polarization so each particle becomes effectively a dipole. Other associated minerals may not be affected. Semiconductive mineral particles entering an electric field permit flow of electrons to the side or end of the particle nearest the positive electrode, leaving the other side positively charged, and the particle has become a dipole by induction.

In practice, the coarsest mineral particles that can be separated reliably are of 20- to 10-mesh size, depending on their specific gravity. The smallest size that can be treated commercially is 100- to 200-mesh. A mass of mixed particles passing through an electrostatic field must be spread out in layers not more than one particle deep so that their individual trajectories cannot intersect. Smaller particles could be treated, but the limitation in area of the separating zone usually makes it uneconomical to treat them. Smaller sized dust tends to adhere to surfaces of apparatus or of larger particles, and therefore it is usually the practice to remove the dusts of finer size from the mixture to be treated. Designs of machines adapted for treating fine dust have been described, but they have not reached commercial adoption.

In Florida two very large commercial installations of conductance-type electrostatic separators with corona charging, work is being done in treating the family of heavy minerals removed from certain sea sands. The titanium minerals, ilmenite and rutile, happen to be the most conductive and are separated from zircon, monazite, quartz, and other minerals of lower conductance (and dielectric constant). Stainless-steel grindings are separated from dirt, sand, and abrasive grits of certain machine shops. Mustard seed is separated from twigs, leaves, sand, dead insects, insect and mouse excreta, and dried dead seeds. Chromite can be separated from the associated silicate minerals. In recent years, pairs of minerals that are not normally separable by any of these processes, if conditioned with a reactive gas, like hydrogen fluoride are surfacially altered to mixtures of good and poor conductors; an example is a mixture of quartz and feldspar. The possibilities of special surface conditioning to enhance differences in physical properties are almost endless and, in their versatility of application, they put electrostatic separations into the class of flotation processes.

Clarification of Aerosols, Cottrell Process

Gases carrying dusts, fogs, fumes, and smokes are common in industry and are frequently the source of economic losses or of nuisance. The process of clarifying these gases is known in the United States as the Cottrell process after the American inventor, and in England as the Lodge process, after the coincident British inventor. The object is to remove the dispersed solid or liquid phase from the true gas. The particles are charged from fine wires at high potential sufficient to cause a corona discharge, positive or negative. The gas and suspended matter become charged by the corona and then migrate at high speed to the oppositely charged electrode where they lose their charge during deposition or contact. The collecting electrode is of large area, and the deposited material is removed by dropping off, or by tapping the collecting electrode, or by keeping the latter flushed with a liquid, usually water, which washes them down.

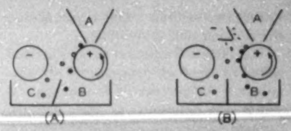

Fig. 2. Conductance separators. Vertical section through two electrodes made of rollers on horizontal axis and oppositely charged

A—Model with purely static field, showing poor-conductive material dropping off without deflection

B—Same as (A), showing poor-conductive material pinned to carrier electrode

The process is widely used and fairly commonly known, but most of the literature avoids discussion of principles and consists mainly of descriptions of installations, their operating details and their efficiency of operation. The forms of apparatus, Fig. 3, are the subject of an extremely extensive patent literature but they normally consist of vertical tubes through which the gas cloud passes, and their inner surfaces act as the grounded collecting electrode while an axial wire acts as the highly charged corona or charging electrode. This, now in wide use, was the earliest form of apparatus, known as the wire-in-pipe form of "treater." The wire-to-plate apparatus consists of vertical plates alternating with rows or curtains of vertical wires; it is less expensive to construct and can be installed in flues, or in expanded flues with the vertical plates parallel to the flow of gases. A third form sometimes used for cleaning the last traces of suspended matter consists of alternating curtains of charged corona wires and grounded collecting wires. Treaters, with flushed collecting electrodes are usually more efficient in collecting dusts of poorly conducting material, providing there is no objection to the collected material being caught in slurry form. "Electric precipitators" are usually more expensive than some of the mechanical gas-cleaning equipment, but freqeuntly they are so much more efficient as to be indispensable. They have had growing use over 40 years.

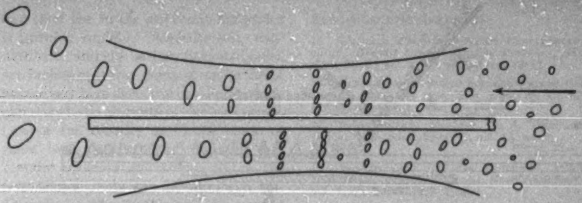

Fig. 4. Electric demulsifier, vertical section. Venturi tube electrode, axial rod electrode; a-c power supply. Water droplets in petroleum coalesced by "chaining" of ovoids of water

Breaking of Water-in-Oil Emulsions

Another invention of Cottrell, put to use during the same period as were gas clarifiers, is the separation of water from petroleum. Oil wells usually produce some water along with the crude petroleum; from various causes, including pumping, some of the water becomes finely divided, and a stable emulsion of water (often a brine) in oil results. Both chemical and electric coagulation processes are in wide use in the United States and around the world, and each has its particular advantages and field of usefulness.

The commonest form of treater for dehydrating such oils can be pictured, see Fig. 4, as a venturi tube connected to the ground, and an axial rod or wire electrode at high potential. Emulsion flowing along such a tube is subjected to a high-potential field; and the droplets of water, being the most conductive component, are distorted into long ovoids oriented toward the charged electrode. The distorted droplets tend to gather into chains between the electrodes separated by thin films of oil, and finally a spark flashing through the chain permits coalescence of the individual small droplets into a few much larger drops that are heavy enough to settle by gravity from the oil phase. The oil layer may be sufficiently treated by one pass or it may require retreatment by several passes through succeeding fields. Petroleum carrying salt or dirt can be churned with water to collect these impurities, and passed through the electric emulsion breaker; the impurities are thus washed out. Similar types of equipment have also been devised for separating precipitated wax from oils, but specialized designs are more efficient.

Either direct or alternating current can be used for this type of separation; high-tension alternating current, being less expensive, is almost invariably used. The Cottrell patents on this type of process were assigned to the California Petroleum Rectifying Corporation, which operated under that name but was ultimately merged with one of the companies using chemicals for coagulation of water droplets.

Electrostatic Spraying

When one of the electrodes creating a high-potential field has a sharp point or edge, at a certain potential drop a corona discharge appears near the sharp edge. When the potential is raised, sparks begin to displace the corona and, on further raise of potential, arcing begins to the opposite electrode. A liquid applied to the small, sharp electrode in the corona state of discharge is sprayed in droplets that are of the same electric sign as that of the corona electrode; the field guides the droplets to the opposite electrode. If the corona electrode is incorporated in a paint spray gun and the articles to be painted are connected to the opposite electrode, or interposed in front of it, the droplets of paint, all being charged and hence repelling each other, form a uniform cloud that precipitates (as in the Cottrell process) uniformly over the surface of the collecting electrode (the article to be painted). The spray gun may be provided with the corona electrode within the gun itself, or the corona electrode may be a grid of small wires close to the spraying nozzle, with the spray passing through the corona zone. Air or steam atomization may be used, or the nozzle may have an axial corona electrode; then all of the atomization would take place by electrical force. The combination of air atomization and electric migration and steering to the target is favored.

Processes of this type have come into wide use for spraying paint uniformly over surfaces with less loss due to overspray that misses the article. The electrical forces deflect much of the overspray to the article, and part of the overspray will even travel to its back side. Spraying of vitreous enamel slip on metal articles to be fired into hard-enameled parts of articles like refrigerators is becoming common. These spraying processes are best adapted to continuous production-line operations but are adapted to intermittent use as well. Spraying of oil onto a ribbon of tin plate passing into a tinning bath and many similar tasks are possible. The principal enterpriser in this field has been Ransberg Electro-Coating Corporation of Indianapolis, Ind.

Drainage of paint to the lower sharp edges of coated articles results in tears or drips of excess paint that are undesirable. If the article is an electrode in a field (either the grounded one or the one at high potential relative to earth), the concentration of field near its sharp edge causes reverse atomization of the tears. If corona potential is not reached, there is another electrostatic effect of lowering the apparent surface tension of a liquid in an intense field so that the tears are

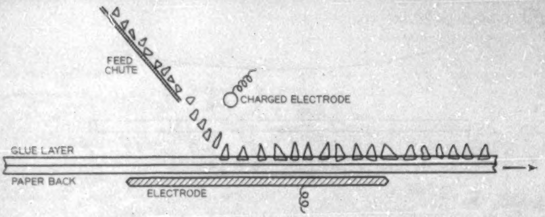

Fig. 5. Electrically oriented sandpaper. Vertical section of continuous machine; sharpest points of abrasive point to densest field

greatly decreased in size by their dripping off. Detearing by electrostatic means is also commercially used.[18]

Field strengths used in these processes vary from 30,000 to 100,000 volts per foot of spacing between electrodes. The field is usually pulsating direct current which is produced by rectification of high-potential alternating current from a variable voltage transformer.

Electrospinning of Fibers

Although commercial electrospinning of fibers has not as yet been attempted, as far as the writer can determine, serious research and development work have been conducted thereon. A list of United States patents in the selected bibliography shows that electrostatic forces were proposed as early as 1902 by Cooley as an aid in spinning artificial fibers. Norton was active in the United States and Formhals from 1934 to 1943 carried forward the development. Formhals took out at least eight United States patents that were ultimately vested in the Alien Property Custodian during World War II. Lastly, Childs assigned to Eastman Kodak Company, Rochester, N. Y., a patent issued in 1944 covering an invention that was an improvement over the others previously issued.[32]

Viscous liquid products, like cellulose acetate in acetone solution, or heat-hardening plastics, or molten glass, issues from a spinneret or other opening and is drawn toward charged electrodes by being charged oppositely in the stream of liquid or through having the spinneret charged. Electric attraction of the advancing fiber tends to stretch and attenuate the fiber before it has firmly frozen or set. Smooth fiber or crinkly shapes can be obtained by rapidly varying electric field or other factors during spinning. The series of patents makes instructive reading.

Electro-Orientation

A wide variety of processes for orienting particulate matter has come into use. Perhaps the earliest application was the preparation of oriented sandpaper. Abrasive grains are normally dropped onto glue on a paper or cloth backing and when the glue is hardened the result is sandpaper or emery cloth. Superior products were produced when the abrasive grains were fed into an electrostatic field maintained between the feeding device and the soft adhesive spread on the backing, or when an electrode was mounted just under it; see Fig. 5. If the most intense field is on the edge of the feeding device or near it and the adhesive-coated fabric is the opposite electrode (usually grounded) the grains of abrasive always have one point or edge that is sharper than any other area on the grain. Being at earth potential when fed in, if they actually contact the high-intensity electrode they take on charge by conduction. If they do not contact it, the sharp points on the particles encourage corona discharge from the charged electrode to the points, and the particles acquire charge of the same sign as the electrode and are repelled toward the coated fabric. The point of the particle is kept oriented toward the most intense field, while it drops, butt end down, into the adhesive film. After drying, the sandpaper thus has the sharpest points or edges facing away from the fabric and is ready to do the most efficient cutting of the article to be sandpapered. The product has another improvement over ordinary sandpaper, resulting from the fact that each abrasive particle is charged during its flight and the charges are all of the same sign so that they are repelled from each other and fall individually onto clean areas of adhesive, uniformly spaced from each other. Closely spaced grains on a sandpaper are often quickly blinded by accumulated cuttings being forced between them. If the abrasive grains are sufficiently spaced apart, this blinding is diminished or avoided. The early enterpriser in this field was Behr-Manning Corporation, Troy, N. Y., but the art has been further developed by other users.

Another field of manufacture, somewhat related, is preparation of velvet and fabrics of similar pile. If threads are cut of the length needed in making velvet and then dropped into place while oriented vertically, the advantage is obvious. Research Corporation pioneered in this.

Permanent electrets (the electric analogue of permanent magnets) have been made by electrical orientation of various materials that can form permanent dipoles. Carnauba wax has a long molecule positively charged at one end and negatively at the other. If melted carnauba wax is placed in a strong electric field to orient the molecules or larger aggregates during congealing of the mass, the result is a permanent electret positively charged at one end and negatively at the other. Magnetite particles magnetized to the maximum condition, suspended in any molten binder and kept oriented by a magnetic field, will give permanent magnets in the same way, but there are many other ways of making them. The field for permanent magnets is growing, but there has been virtually no known way of making permanent electrets for a similar wide series of industrial applications.

The same means of orienting anisotropic particles in an electrostatic field during setting of a resin in a molten binder permits preparation of light polarizing articles or oriented sheets of condenser material like rutile particles (whose dielectric constant parallel to their minor crystallographic axis is 89 but is 173 when parallel to the major axis). This latter article leads to lowest dielectric loss and reduction in power factor, according to the Western Electric Products, New York, N. Y.

Conductivities of gold sols increase in an electrostatic field, and it has been shown that particles have oriented into countless chains of metal particles, which accounts for increased conductance.

The electroviscous effects in liquids and suspensions of solids in liquids are caused by a number of factors whose effects are additive. Depending on the geometry of flow an increase or decrease in viscosity can take place due to electro-orientation. Flat-flake and needle shapes contribute to this effect.

The patent literature abounds in examples of applications of such phenom-

Vol. 7
Pt. 1
1956

ena. Jacobs is interested in hardenable plastics reinforced by flake mica. If, during heating of the plastic in the liquid condition, the mica flakes are electrically oriented, the final hard product has a dielectric strength normal to the faces of the oriented flakes which is different from that parallel to them. A particularly clever application of electrostatics is that by Gwyn and Williams for packing sheet glass for shipment with sawdust or similar soft material for filler between the sheets of glass to prevent rubbing; see selected bibliography. The sheets of glass approaching the packer's box on a conveyor belt are charged by contact with an electrode at say 70,000 volts or rubbed by a silk roller to charge the surface. Sawdust sprinkled over the surface adheres until the sheet of glass is placed and another similarly placed on top of it. Dissipation of the charge leaves the glass packed with a minimum of spacing between sheets and yet adequately protected against rubbing together during transit or handling.

The use of electrified particles to point out the location of flaws in enamels and glazes was indicated by Jones, see selected bibliography, and developed for commercial use by the Magnaflux Corporation of Chicago, Ill., with the trade name of Stratiflux. Steel, coated with vitreous enamel, can be positively charged and fine talc dust suspended in air blown past a negative electrode onto the enamel surface. The electrified dust adheres only to cracks or other flaws in the enamel. If the body coated with enamel is nonconducting, a special penetrating aqueous solution is absorbed through the defects first.

All of the applications of electroorientation cannot be covered here; however zerography or "electrical printing and copying" should be mentioned as developed mainly at the Battelle Institute, Columbus, Ohio, which makes a more complex application of the phenomena just mentioned.

Piezoelectric solids become charged into dipoles, oppositely charged at opposite ends by being stressed. Pyroelectric phenomena are closely related and probably depend on thermal stresses bringing about piezoelectric charging. The reverse phenomenon is electrostriction or changes in dimension of aniosotropic crystals with different dielectric constants in the different crystallographic directions when an electric unidirectional field is impressed on the crystal. The ferroelectric semiconductors of recent development are materials of this kind and their use in the electronic industries is growing rapidly. Rochelle salt, seignett salts, and the barium titanate bodies are included in this group of materials of excessively high dielectric constants which can store large amounts of electric energy. One of the theories as to the cause of these high dielectric constants is that certain electrons in the atoms of the ferroelectric body can be displaced sufficiently by the electric field to convert the body to a mass of tiny atomic dipoles all oriented similarly until the imposed electrostatic field is removed.

What has been said gives point to the thought that electrostatics, a relatively neglected field in electrical technology, has been put to increasing use by industry and that the field of further application and invention is still quite uncultivated.

Transcendental Function Analogue Computation with Magnetic Cores

D. H. SCHAEFER
ASSOCIATE MEMBER AIEE

R. L. VAN ALLEN
ASSOCIATE MEMBER AIEE

SQUARE loop magnetic cores used in conjunction with switching transistors can be made to perform a great number of arithmetical operations. Previous papers have shown how these elements can be used to obtain 4-quadrant multiplication[1] and division[2]. This paper presents a basic circuit and shows how this circuitry can be utilized to obtain various sorts of computations. Specifically, experimental data are presented showing results obtained with the use of the circuit to obtain an output voltage proportional to the square root and other fractional powers of an input voltage, the arc sine of an input voltage, the sine of an input voltage and the product of two voltages. These are only a few of the possible outputs which are theoretically attainable.

The computing element described here is completely static in its operation. The output is in the form of current or voltage pulses whose average values are a specific function of one or two input voltages.

Basic Computing Circuit

Fig. 1 shows the basic circuit used for all the functions described in this paper. The magnetic core shown is of the "rectangular" or high-remanance type, aud type *p-n-p* transistors are used only as switches, appreciably enhancing their reliability and power-handling capacity. The voltage e_{ac} is a periodic voltage whose wave shape is dependent upon the computation desired and whose magnitude is great enough to drive the core from negative to positive saturation in a half-cycle. The voltage e_1 is in all cases a direct voltage of the indicated polarity. The voltage e_2 is usually a direct voltage, although for some computations it assumes other forms. When both of the input voltages e_1 and e_2 are direct voltages, the output voltage e_0 consists of a series of rectangular pulses whose height is proportional to e_2 and whose width is proportional to some function of e_1. Therefore the average output is proportional to $e_2 \times f(e_1)$, the particular function f depending upon the shape of e_{ac}.

In brief, the circuit operates as follows: When e_{ac} has the polarity shown, the emitter-collector resistance of transistor 1 is low, so the voltage e_1 is applied directly across the core windings and changes the flux level of the core from positive saturation to some flux level between positive and negative saturation, the amount of change being proportional to the magnitude of e_1. During this half-cycle, the emitter-collector resistance of transistor 2 is high and no voltage appears across the output resistor.

When e_{ac} has a polarity opposite to that which is shown in Fig. 1, the voltage e_{ac} itself is applied directly across the core windings in such a direction as to change the flux level of the core back to positive saturation. When it is remembered that e_{ac} has a value such as to enable it to reset completely the core on any given half-cycle, it is obvious that when e_{ac} is negative, the core will become saturated at some point during the half-cycle unless e_1 on the previous half-cycle has set the flux at negative saturation. During the portion of this negative half-cycle of e_{ac} that the core is unsaturated, the transformed voltage e_{ac} is applied to the base of transistor 2, allowing it to conduct, and therefore the voltage e_2 appears across the output resistor. After saturation of the core, only negligible voltage can be transformed to the base of transistor 2, therefore its emitter-collector impedance is high and the output voltage again falls to zero. The output voltage exists only when e_{ac} is negative and the core is unsaturated. How the shape of e_{ac} affects the length of time it will take to saturate the core during the negative half-cycle of e_{ac} will be examined in a moment.

To be convinced that the circuit will operate as just described, the reader should be aware of the following rule governing the switching characteristics of *p-n-p* transistors: If the base is more positive than both the emitter and collector, the emitter-collector impedance is very high, approximating an open circuit; if on the other hand, the base is more negative than both the emitter and collector, the emitter-collector impedance is near that of a short circuit as the transistor is saturated. If this rule is applied and if the effect of transformed voltages on transistor number 2 is kept in mind, it will be seen that the three modes of operation of the circuit are as shown in Figs. 2(A), (B), and (C), Fig. 2(A) being the equivalent of Fig. 1 when e_{ac} is positive; Fig. 2(B) the equivalent when e_{ac} is negative and the core is unsaturated; and Fig. 2(C) the equivalent when e_{ac} is negative and the core is saturated.

Theory of Computation

The deferred question of the time required to saturate the core on the negative half-cycles of e_{ac} will now be examined. It should be recalled that during the positive half-cycle of e_{ac}, the flux level of the core was changed by an amount $\Delta\phi$ that was proportional to the value of e_1 during that half-cycle. Therefore, during the negative half-cycle of e_{ac}, $\Delta\phi$ volt seconds must be "read out" of the core by e_{ac} before the core will saturate. This can be mathematically stated as

$$\int_0^{t_s} e_{ac}dt=\Delta\phi=ke_1 \qquad (1)$$

where time is measured beginning with the negative half-cycle of e_{ac} and t_s is the time at which the core saturates. It is wished to solve for the value of t_s. If, for a first example, e_{ac} is a square wave, i.e., if e_{ac} equals a constant K during each half-cycle, then equation 1 can be written as

$$\int_0^{t_s} Kdt=ke_1 \qquad (2)$$

$$K\int_0^{t_s} dt=ke_1 \qquad (3)$$

$$\text{or } t_s=\frac{ke_1}{K} \qquad (4)$$

Equation 4 states that the time necessary to saturate the core will be proportional to e_1. Therefore the width of the output pulse will be proportional to e_1. The height of the output pulse is e_2. The average value of the output voltage will therefore be proportional to the product of e_1 and e_2, if e_{ac} is a square wave. The circuit in this case is a single-quadrant version of the multiplier presented in reference 1.

Paper 56-134, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 21, 1955; made available for printing November 30, 1955.

D. H. SCHAEFER and R. L. VAN ALLEN are with the U. S. Naval Research Laboratory, Washington, D. C.

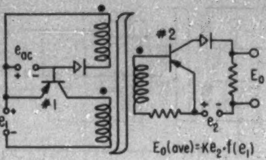

Fig. 1. Basic computer circuit

As a second example, let e_{ac} have the form Kt during the read-out half-cycle of e_{ac}. A triangular wave form will, for instance, provide such a ramp function. Equation 1 now becomes

$$\int_0^{t_s} Kt\,dt = ke_1 \tag{5}$$

$$\int_0^{t_s} t\,dt = \frac{ke_1}{K} \tag{6}$$

$$t_s^2 = \frac{2ke_1}{K} \tag{7}$$

$$t_s = \sqrt{\frac{2ke_1}{K}} \tag{8}$$

Under these circumstances, equation 8 shows that the time necessary to saturate the core will be proportional to the square root of e_1. Therefore the width of the output pulse will be proportional to the square root of e_1, and the average output will be proportional to $e_2 \times \sqrt{e_1}$.

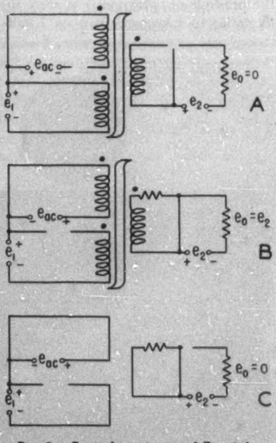

Fig. 2. Equivalent circuits of Fig. 1 for

A—e_{ac} positive
B—e_{ac} negative and core unsaturated
C—e_{ac} negative and core saturated

Table I. Output Voltages Produced by Various Wave Forms of e_2 and e_{ac}

e_1	e_2	e_{ac}	E_0 (ave)
d-c	d-c	square wave	$e_1 \times e_2$
d-c	d-c	Kt	$e_2\sqrt{e_1}$
d-c	d-c	Kt^n	$e_2 \times e_1^{\frac{1}{n+1}}$
d-c	d-c	$\cos \omega t$	$e_2 \times \sin^{-1} ke_1$
d-c	$\cos \omega t$	square wave	$\sin ke_1$
d-c	Kt^n	square wave	e_1^{n+1}
d-c	$f(t)$	square wave	$\int_0^{ce_1} f(t)dt$
d-c	Kt^n	Kt^m	$e_1^{\frac{n+1}{m+1}}$
d-c	$\cos \omega t$	Kt	$\sin k\sqrt{e_1}$
d-c	Kt	$\cos \omega t$	$(\sin^{-1} ke_1)^2$

Generalizing this example, it can be seen that if e_{ac} has the form Kt^n, the output will be proportional to e_1^x where the exponent x equals $1/(n+1)$. Letting n equal 2, for instance, will make the output proportional to the cube root of e_1. It will be shown that, experimentally, exponential outputs between 0.5 and 0.8 could be obtained with the use of e_{ac} wave shapes formed from resistance-capacitance networks modifying a square wave.

If one wishes to obtain an output proportional to the arc sine of the voltage e_1, it is necessary that e_{ac} be a cosine. If $e_{ac} = K \cos \omega t$, equation 1 becomes

$$K\int_0^{t_s} \cos \omega t\; dt = ke_1 \tag{9}$$

$$\frac{K}{\omega}\sin \omega t_s = ke_1 \tag{10}$$

$$\omega t_s = \sin^{-1}\frac{\omega k e_1}{K} \tag{11}$$

$$\text{or } t_s = \frac{1}{\omega}\sin^{-1}\frac{\omega k e_1}{K} \tag{12}$$

In practice, the cosine function can be easily obtained from a sinusoid voltage in series with a core that saturates in the middle of each half-cycle. This will be further detailed in the section on the practical circuit.

From this it can be seen that theoretically the output can be made proportional to any function of e_1 if e_{ac} can be formed into the shape of the derivative of the inverse of the desired function. For instance, if the voltage e_{ac} had the form $1/\sqrt{a^2 - t^2}$ the output would be proportional to the sine of e_1. To obtain such a time function is, to put the matter mildly, not easy. There is a relatively simple way, however, to obtain an output proportional to the sine of the input, and that is to let e_{ac} be a square wave and have the voltage e_2 assume the form of a cosinusoid. Having e_2 able to assume various wave forms in fact increases the number of functions easily obtainable by a large number.

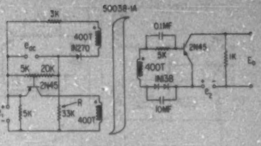

Fig. 3. Basic experimental circuit; core material Orthonol

The theory of the sine output element using a square wave e_{ac} and cosinusoid e_2 is as follows. Equation 4 states that with e_{ac} a square wave t_s will be proportional to e_1. The average voltage across the output resistor will be proportional to the integral of e_2 from zero to t_s. Mathematically

$$E_0(\text{ave}) = \int_0^{t_s} e_2\,dt \tag{13}$$

In the circuit under discussion, e_2 equals $C \cos \omega t$ and, from equation 4, $t_s = ce_1$ where C and c are constants. Therefore

$$E_0 = C\int_0^{ce_1} \cos \omega t\; dt \tag{14}$$

$$\text{or } E_0 = \frac{C}{\omega}\sin \omega c e_1 \tag{15}$$

Again the cosine function may be obtained by letting a sinusoidial voltage saturate a core.

If e_{ac} is a square wave and e_2 has the form Ct^n a derivation analogous to the foregoing shows that the output will be proportional to e_1^{n+1}. If e_2 is a ramp function, the output will be proportional to the square of the input, while if e_2 has a

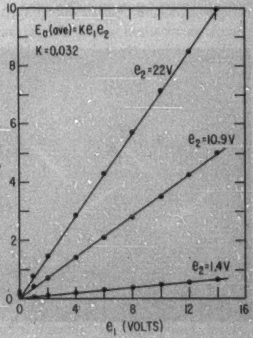

Fig. 4. Output proportional to product

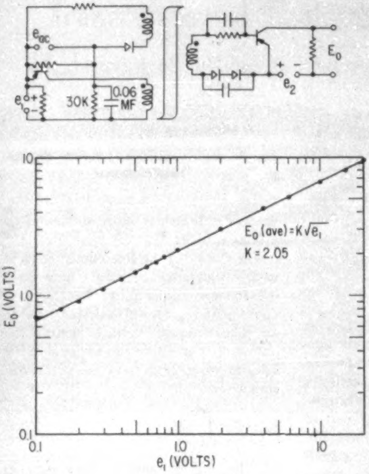

Fig. 5 (left). Output proportional to square root

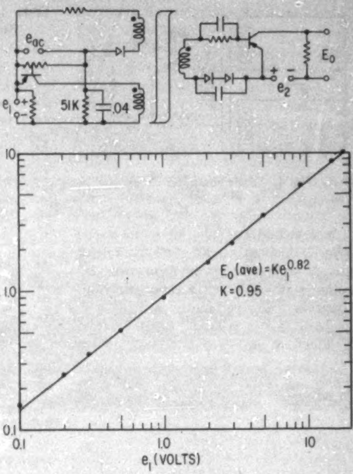

Fig. 7 (right). Output proportional to input raised to 0.82 power

parabolic wave form, for instance, the output will be proportional to the cube of the input.

Table I summarizes various combinations of voltage wave forms and the outputs they produce. Complex functions can be solved in two ways. One is to put functional wave forms on both e_{ac} and e_2. For instance, if e_{ac} has a trianglar wave form and e_2 a cosinusoidal form, the output will be proportional to the sine of the square root of e_1. If the two voltages are interchanged so that e_{ac} is cosinusoidal and e_2 is triangular, the output will be proportional to the square of the arc sine of e_1. As shown in the Table I, a wide variety of exponential outputs can be obtained by putting exponential wave forms on both e_{ac} and e_2.

The second method of building complex functions is to cascade elements. This can be done as it is the average value of e_1 that determines the amount of flux reset. By putting elements in series and by using each element to its full potentiality, exceptionally complex functions can be quickly synthesized. It should, of course, be realized that every added element in series delays the time in obtaining the answers by 1 half-cycle of the supply frequency.

Practical Considerations

The precision or accuracy of any of the computations performed by the analogue devices described in this paper are of the order of 1 per cent (%) or 2% of full-scale output. To insure this accuracy over the entire operating range, a reasonable amount of care should be taken with the choice of the various supplies; in particular, the source of e_{ac} and e_1. Since the principle of operation is to store information in a magnetic core on 1 half-

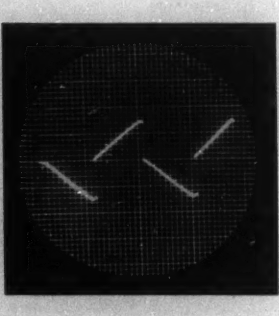

Fig. 6. Wave form of e_{ac} used for extracting square root

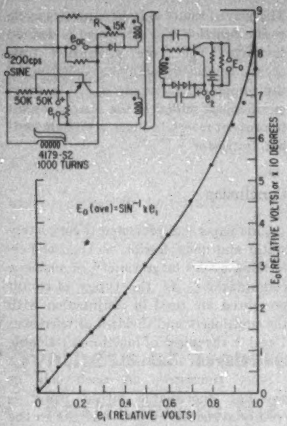

Fig. 9. Output proportional to arc sine

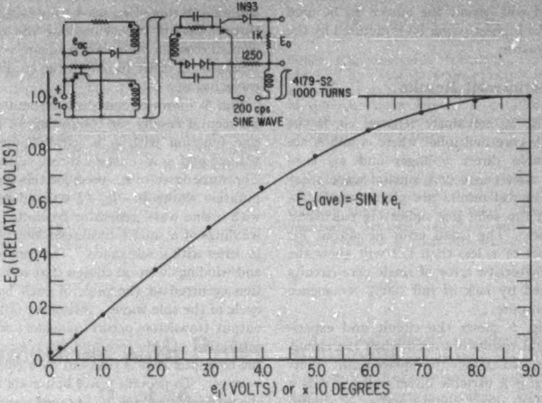

Fig. 11. Output proportional to sine

cycle and then to read out of the core the same information as a different function of time on the next half-cycle, a certain amount of work must be done in either case. Therefore the source voltage for read-in or read-out must be capable of delivering a small amount of power with good regulation. In the several experimental circuits tested, the input impedances have not been greater than several thousand ohms, and hence, the source impedance of the supplies have been usually 1,000 ohms or less.

When a voltage is applied to the windings of a square hysteresis loop core material, magnetizing current must be supplied before any flux change can be produced. This may have detrimental effects when the voltage e_1 is low and is supplied from a high-impedance source. The effect will be to delay the action of e_1 such that no output will be obtained until e_1 has been increased sufficiently to produce magnetizing current. Therefore it is necessary by some means to provide a magnetizing current bias. The resistor R in Fig. 3 has been added to the circuit primarily for this purpose; it is the actual circuit used for the multiplier and, with minor changes, for the other computations.

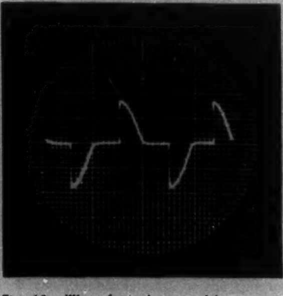

Fig. 10. Wave form of e_{ac} used for arc sine calculation

The effect of temperature on transistors used as switches is negligible, provided there is adequate switching voltages to hold the transistors in one of two states, saturation or cutoff. At high temperatures, the collector-cutoff current will increase appreciably unless a blocking voltage is provided which holds the base slightly positive with respect to the emitter. The switching transistor in the output circuit of the basic computer, Fig. 1, has no provision for a positive blocking voltage on the base. For reliable operation at elevated temperatures, it is necessary to add a small positive voltage of less than 1 volt which may be provided from a bias source; however, this requires an additional d-c source which can be eliminated by diodes in parallel with a capacitor, as shown in the output circuit of Fig. 3. The current pulses out of the base, switching the transistor charge the 10-microfarad capacitor to approximately 1 volt, which is twice the forward voltage drop of a single *1N138* silicon diode.

The 5,000-ohm by-pass resistor also shown in the base circuit provides base current limiting to the low-frequency components of the base voltage pulses transformed by the core. The 0.1-microfarad capacitor passes the high-frequency components to aid in precise time switching of the transistor.

The experimental computing circuits discussed in this paper have been operated at a supply frequency of 200 cycles per second. Difficulties arise when the frequency is increased in this single-core circuit, whereas, the 2-core, 4-quadrant multiplier[1] has been operated at 5 kc, maintaining an accuracy of ±1%. As explained in reference 1, the single-core multiplier has a small output for zero input at e_1 which is produced by the core having less than 100% remanence. This error appears in the output as narrow pulses, which at low frequency contribute less than 1% error but at higher frequencies may become an appreciable percentage of full output, unless some provision is made such as in the 2-core circuit to eliminate this difficulty. An operating frequency of 200 cycles per second was chosen to obtain these data in order to present the circuit in its simplest form and still exhibit 1% accuracy.

The experimental data presented in this paper were obtained at a maximum power level of 0.1 watt. The *2N45 p-n-p* type of transistor can be used to switch power to about 2 watts, provided sufficient base drive is available. This is an important factor to consider in proposed applications of this type of computer circuitry since in many control applications it is required to provide a unique control function at high-power levels. The proper choice of output transistor and power source from which e_2 is supplied will permit the output to be used at the highest power level dictated by the transistor.

Experimental Results

Fig. 3, previously referred to, is the single-core multiplier where e_1 and e_2 are variable direct voltages and e_{ac} is a 200-cycle-per-second square wave. Experimental results are plotted in Fig. 4 with the solid line indicating calculated values. The small error in output for values of e_1 less than 1/2 volt show the characteristic error of single-core circuits caused by lack of full 100% remanence of the core.

Fig. 5 shows the circuit and experimental results obtained when the circuit is used to extract the square root. Voltage e_1 is a variable direct voltage, e_2 is a constant direct voltage and e_{ac} is a ramp function obtained by adding a triangular and square wave form 90 degrees out of phase. The wave form of e_{ac} is shown in shown in Fig. 6. As previously mentioned, the wave form of e_{ac} could be a triangular wave; however, the wave form shown in Fig. 6 is a more efficient one for this application since the ramp function is continuous over a complete half-cycle. Actual observed points are plotted with the solid line indicating calculated values.

Fig. 7 shows the circuit and experimental results for a fractional exponent of 0.82; e_1 was a variable direct voltage with e_2 a constant direct voltage. Outputs proportional to input voltage e_1 raised to the 0.6 and 0.54 power were also experimentally obtained with different wave forms for voltage e_{ac}. Fig. 8 shows the wave forms of e_{ac} used to obtain the three different exponents and the networks necessary to modify a square-wave generator in order to obtain the required wave forms.

Fig. 9 shows circuit diagram and experimental results for computing an arc sine function with e_1 a variable direct voltage and e_2 a constant direct voltage. The wave form of e_{ac} used for this computation shown in Fig. 10 was obtained with a sine wave generator connected to windings of a square hysteresis loop core in series with a resistance. The core size and windings were so chosen that saturation occurred at the peak of each half-cycle of the sine wave. Switching of the output transistors occurs coincident with saturation of this core and for 1/4 cycle the computer core is read-out by a cosine voltage. To provide a full half-cycle for the read-in period for e_1, the input transistor is switched by the sine wave generator instead of the voltage e_{ac}. The compensating resistance R is shunted across the rectifier in this case for best results. Because the core does not possess 100% remanence and because of the nature of the arc sine function, a constant was added to the output which displaced the response curve in a positive direction equivalent to a phase shift of 5 degrees. To correct for this constant, a direct current was introduced in the output load resistance equal and opposite to the amount of the displacement.

Fig. 11 shows the circuit diagram and results of a computing circuit whose output is proportional to the sine of the input voltage e_1, where e_1 is a variable direct voltage. Supply voltage e_{ac} is a square wave as used for the multiplier. The wave form of e_2 is the same 1/4-cycle cosine function of Fig. 10 and is derived similarly. The core saturation time occurs coincident with the switching of the square-wave supply e_{ac}. An extra rectifier was added in the output circuit to prevent reverse voltage across the output transistor.

Conclusion

This paper has presented a completely static and quite flexible method of performing a very large variety of analogue computations. If the types of circuit presented are used in conjunction with the multipliers and dividers of references 1 and 2, the range of functions attainable is even further increased.

Since transistors are used only as switches, appreciable output power is readily available. Power outputs on the order of watts are obtainable, for instance, with nominal 150-milliwatt transistors.

In summary, a rugged, fast static method of performing analogue computation has been presented that is dependent only upon the wave form of periodic functions and the ability of a high-remanence magnetic core to store a given number of volt-seconds for a half-cycle of a supply frequency.

Discussion

A. J. Schiewe (Purdue University, W. Lafayette, Ind.) and **K. Chen** (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors are to be commended for their success in extending the pulse modulation technique to obtain transcendental function analogue computation with magnetic cores and switching transistors. The flexibility of the basic computer circuit is particularly impressive in producing a great variety of transcendental functions as listed in Table I. We have developed a number of analogue circuits different from the authors' to perform various transcendental functions, but also based on the principle of width and amplitude modulation of voltage pulses of specific shapes. An important difference between our circuitry and that of the authors, is that only switching transistors are used in our basic circuits. No magnetic cores are used because our experience with pulse-width modulation by means of magnetic cores made of presently available materials showed a lack of sharpness in the edges of the pulses, especially at frequencies around and above 1 kc. Since magnetic cores are not used in our basic circuits, no integration of voltage with respect to time is accomplished as given by equation 1 of this paper. However, transcendental functions can easily be generated with switching transistors alone. The wave forms shown in Figs. 12 and 13 illustrate the basic principles of our logarithmic and antilogarithmic circuits, respectively. In the logarithmic circuit, the direct input voltage E_i is superimposed on a train of exponential voltage pulses e_L. The difference between these voltages $(e_L - E_i)$, is used to control a

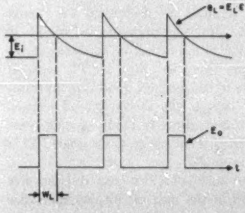

Fig. 12. Basic principles of the logarithmic circuit

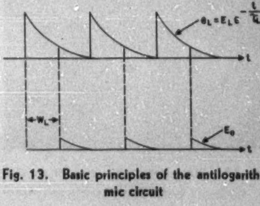

Fig. 13. Basic principles of the antilogarithmic circuit

transistor switch such that a constant voltage is switched on the load when (e_L-E_t) is positive and switched off the load when (e_L-E_t) is negative. The output voltage is, therefore, a train of rectangular pulses with fixed amplitude and frequency and with a width W_L given by the equation:

$$W_L=-\tau_L \ln \frac{E_t}{E_L}$$

which is derived by the relation:

$$E_t=E_L\epsilon^{-\frac{W_L}{\tau_L}}$$

Thus, the average output voltage is a logarithmic function of the input voltage E_t. In the antilogarithmic circuit, a transistor switch is used to modulate the width of the exponential pulses e_L that will appear on the load. The input information is contained in the pulse width W_L of a train of rectangular pulses (not shown in Fig. 13) which are used to modulate the on-off time of the transistor switch. The average output is, therefore, an antilogarithmic function of the input pulse width W_L as shown in the following equation:

$$E_0(\text{avg})\cong f\int_{W_L}^{\infty} E_L\epsilon^{-\frac{t}{\tau_L}}\,dt$$

$$=E_L\tau_L f\,\text{antiln}\left(-\frac{W_L}{\tau_L}\right)$$

Other transcendental functions can be obtained by using the same principle if the exponential pulses are replaced by pulses of different wave forms. A detailed description of our circuits is intended to be published in the future.

D. H. Schaefer and R. L. Van Allen: We are happy to see alternate methods of performing analogue computations. The experimental results obtained with these circuits will be of great interest.

Synthesis of Transfer Functions with Poles Restricted to the Negative Real Axis into Two Parallel R-C Ladders and an Ideal Transformer

M. G. MALTI
MEMBER AIEE

HUN HSUAN SUN
ASSOCIATE MEMBER AIEE

Synopsis: This paper presents a method of synthesizing a circuit to obtain a transfer function whose poles lie on the negative real axis and whose zeros lie anywhere in the complex frequency plane including the positive real axis by means of two parallel resistance-capacitance (R-C) ladders and an ideal transformer. The polynomial in the numerator of the given transfer function is first resolved into the difference of two component polynomials whose zeros are all negative real numbers. The method of resolution is based on conditions for collinearity of points that represent *n*th degree polynomials (with real coefficients) in *n*-dimensional space. The two component polynomial fractions for the given transfer function are then synthesized into two R-C ladders and the resulting network is the parallel combination of these two ladders through an ideal transformer and terminated by another R-C ladder. The method applies to more generalized cases and usually gives a network that contains less resistive and capacitive elements than any of the other methods available. If the resolution of the numerator polynomial is as a sum of polynomials instead of a difference, more than two components may be required. An expression for the upper bound to the least number of such components is also included in the paper.

IN RECENT YEARS there has been considerable interest in the question of how a transfer function may be realized as a linear passive network containing a minimum number of resistances and capacitances. Methods have been derived so that a transfer function whose poles and zeros are all real and negative can be synthesized into an R-C unbalanced ladder.[1-3] Further developments have been made to extend these methods to the transfer function containing complex zeros, while the number of resistive and capacitive elements has been kept low by various methods of synthesis.[4-6]

Consider a rational fraction of the complex frequency variable p, as:

$$\frac{P(p)}{Q(p)}=\frac{p^n+a_1p^{n-1}+a_2p^{n-2}+\ldots+a_n}{p^m+b_1p^{m-1}+b_2p^{m-2}+\ldots b_m}$$

$$=\frac{(p-p_1)(p-p_2)\ldots(p-p_n)}{(p-q_1)(p-q_2)\ldots(p-q_m)}\quad n\leq m \quad (1)$$

where $p_1p_2\ldots p_n$ may be real and complex numbers, $q_1q_2\ldots q_m$ are negative real and simple. The coefficients of $P(p)$ are real numbers while the coefficients of $Q(p)$ are restricted to be positive and real as governed by the nature of their roots.[7] It is required to realize the rational fraction within a constant multiplier K as the transfer function of the ratio of the input and output voltages of an unbalanced R-C network, Fig. 1, as:

$$H(p)=\frac{E_2}{E_1}=K\frac{P(p)}{Q(p)} \qquad (2)$$

A method, already described in the literature,[4,6] is to realize the given rational function into a network containing a number of R-C ladders in parallel. The procedure is first to resolve the numerator polynomial $P(p)$ into a sum of component polynomials that contain only real negative zeros while the denominator polynomial $Q(p)$ is left unchanged. Each component polynomial together with the denominator polynomial is then synthesized into an R-C ladder. The sum of these component functions representing the transfer function is then realized by the parallel combination of these component ladders with the proper gain adjustment. This method applies only to the transfer function whose zeros lie on the left-hand side of the complex frequency plane and the number of parallel R-C ladders used has been found to be

$$t\leq\frac{n+1}{2}\quad\text{if } n \text{ is odd}$$

$$\leq\frac{n}{2}+1\quad\text{if } n \text{ is even} \qquad (3)$$

n is the degree of the numerator.

If the numerator polynomial $P(p)$ contains both negative real and complex zeros, the number of parallel R-C ladders can be reduced by first factoring the negative real zeros, as:

This paper is a condensation of Dr. Sun's Ph.D. Thesis, part I, at Cornell University.

The authors wish to express their gratitude to Dr. H. Sohon, University of Pennsylvania, for his valuable suggestions and encouragement; Dr. F. C. Morneghem, Institute Tech. de Aero, Est São Paulo, Brazil, for suggesting the collinear conditions of points represented by polynomials; and S. S. Abhyanker, Harvard University, for suggesting the proof of the uppermost bound for the least number of component polynomials required in the resolution of a polynomial.

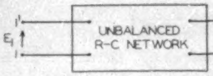

Fig. 1. Unbalanced R-C network

$$P(p^n)=P_1(p^{n-r})\times P_2(p^r) \quad (4)$$

where $P_2(p^r)$ is the polynomial formed by the r number of nonpositive real zeros and $P_1(p^{n-r})$ is the polynomial formed by the remaining zeros. The resolution of $P_1(p^{n-r})$ will therefore result in a smaller number of parallel ladders as:

$$\begin{aligned} t &\leqslant \frac{(n-r)+1}{2} && \text{if } (n-r) \text{ is odd} \\ &\leqslant \frac{(n-r)}{2}+1 && \text{if } (n-r) \text{ is even} \end{aligned} \quad (5)$$

Then by the application of Norton's network theorem,[6] the rational fraction formed by the zeros of $P_1(p^{n-r})$ together with a number of poles equal to one less than the number of zeros is synthesized into parallel R-C ladders, while the rational fraction formed by the zeros of $P_2(p^r)$ and the remaining poles is synthesized into an R-C termination ladder connected to the output of the parallel R-C ladders. If r is equal to zero, or the given transfer function contains no negative real zeros, then equation 5 reduces to equation 3 while the termination ladder becomes a unity resistance as originally derived by Guillemin.[4] The number of R-C elements used in each ladder has been further reduced by the use of a zero-cancellation device. This method has been extended to the transfer function containing zeros in the whole complex frequency plane excluding the positive real axis by the use of a surplus factor.[5] If the zeros of the given transfer function are close to the positive real axis, the degree of the equation which represents the surplus factor becomes extremely large. This, in turn, requires the addition of a large number of R-C elements.

The method to be presented in this paper, however, reduces the number of parallel R-C ladders used to only two without increasing the degree of the numerator polynomial of the given transfer function, and applies to the transfer function whose zeros lie in the whole complex frequency plane including the positive real axis. A method is developed to resolve any polynomial with real coefficients into the difference of only two component polynomials each containing negative real zeros. The synthesized network will, therefore, contain only two R-C ladders with their inputs in parallel, their output connected to an additional R-C ladder through an ideal transformer. The ideal transformer is necessary in order to avoid a circulating current.[8] A theorem is presented to show that the uppermost bound of the minimum number of component polynomials whose zeros are negative real and whose sum is equal to the given polynomial is the least integer greater than $n/2$, where n is the degree of the given polynomial.

A numerical example is given to show the method of synthesizing a transfer function with zeros unrestricted and poles on the negative real axis of the complex frequency plane into two parallel R-C ladders and an ideal transformer.

Resolution of a Polynomial with Real Coefficients into the Difference of Two Component Polynomials Each with Real Negative Zeros

It has been found that a polynomial with real coefficients in a single variable can be represented as a point in a geometrical space.[9] Therefore, we can say that a polynomial of

$$M(x)=x^n+a_1x^{n-1}+a_2x^{n-2}+\ldots+a_n \quad (6)$$

where $a_1a_2 \ldots a_n$ are real numbers, is a point defined by its coefficients as co-ordinates in an n-dimensional space represented by:

$$N(a_1a_2\ldots a_n) \quad (7)$$

The coefficients of the highest degree term is adjusted to be unity. A polynomial of the form

$$R(x)=x^n \quad (8)$$

is thus the point that coincides with the origin.

A polynomial with positive real coefficients can therefore be regarded as a point defined by its coefficients as co-ordinates in an n-dimensional space that lies in a domain whose co-ordinates are all positive. Such a domain shall be referred to as the positive domain. The n-dimensional space can be considered as divided into 2^n separate domains; for example, if $n=2$, the domains are quadrants, if $n=3$, the domains are octants, and so forth.

A discriminant of a polynomial is the equation that determines whether the given polynomial contains real zeros or not. Thus, from the foregoing discussion, a discriminant shall be defined as the boundary between the real-root domain and the complex-root domain. The discriminants of polynomials lower than fourth degree have been determined[7] and can be expressed in terms of the coefficients of the given polynomials. There are various methods available to determine whether an nth degree polynomial contains real zeros or not, but a unique expression in terms of the coefficients of the given polynomial that satisfies the foregoing condition is necessary in order to be regarded as a discriminant. Appendix I gives an expression in the form of determinants that serves as a criterion for negative real zeros of a given nth degree polynomial and can thus be regarded as the discriminant of the polynomial.

This basis will be used to distinguish the polynomials that contain only real zeros from those containing complex zeros. The space where the polynomial is represented is separated into two domains, namely, the real-root domain and the complex-root domain. The real-root domain is defined as that portion of the n-dimensional space which contains all the points $N(a_1a_2 \ldots a_n)$ that make the polynomial $M(x)=x^n+a_1x^{n-1}+\ldots+a_n$ have only real zeros. Similarly, the complex-root domain shall be defined as that portion of the n-dimensional space which contains the points $N(a_1a_2 \ldots a_n)$ that make the polynomial $M(x)=x^n+a_1x^{n-1}+\ldots+a_n$ have one or more pairs of imaginary or complex zeros. It is, therefore, evident that those points represented by $N(a_1a_2 \ldots a_n)$ which are not in the real-root domain must lie in the complex-root domain.

The problem in R-C network synthesis is to express a polynomial that lies in the complex-root domain as a linear combination of as few as possible component polynomials that lie in a domain common to the positive domain and real-root domain. The former condition is required by the fact that the coefficients of a polynomial with negative real zeros must be positive.[7] Now consider the following three polynomials:

$$P(x)=x^n+a_1x^{n-1}+a_2x^{n-2}+\ldots+a_n \quad (9)$$

$$B(x)=x^n+b_1x^{n-1}+b_2x^{n-2}+\ldots+b_n \quad (10)$$

$$C(x)=x^n+c_1x^{n-1}+c_2x^{n-2}+\ldots+c_n \quad (11)$$

where $P(x)$ is the given polynomial and $B(x)$ and $C(x)$ are its component polynomials. From these discussions, they can be represented by the following three points:

$$G(a_1a_2\ldots a_n) \quad (12)$$

$$H(b_1b_2\ldots b_n) \quad (13)$$

$$F(c_1c_2\ldots c_n) \quad (14)$$

If the polynomials of equations 9, 10, and 11 are linearly dependent, then their points represented by equations 12, 13, and 14 must be collinear.[9] As three points are the least number of points for the collinear condition in n-dimensional space, therefore, the minimum number of component polynomials has been chosen as two. By a well-known theorem of linear dependence,[9] it must be true that every 3-rowed determinant of the following matrix

$$\left\|\begin{matrix} 1 & a_1 & a_2 & \cdots & a_n \\ 1 & b_1 & b_2 & \cdots & b_n \\ 1 & c_1 & c_2 & \cdots & c_n \end{matrix}\right\| \tag{15}$$

must vanish, or the following determinant must be equal to zero, that is,

$$\begin{vmatrix} 1 & a_i & a_j \\ 1 & b_i & b_j \\ 1 & c_i & c_j \end{vmatrix} = 0 \tag{16}$$

where i and j are both positive integers such that $1 \leqslant i < n$, $1 \leqslant j \leqslant n$ and $i \neq j$.

Expanding equation 16 on the last column and equating to zero gives:

$$\begin{vmatrix} 1 & a_i \\ 1 & c_i \end{vmatrix} b_j + \begin{vmatrix} 1 & b_i \\ 1 & a_i \end{vmatrix} c_j = \begin{vmatrix} 1 & b_i \\ 1 & c_i \end{vmatrix} a_j$$

or

$$k_1 b_j + k_2 c_j = a_j \tag{17}$$

where

$$k_1 = \frac{c_i - a_i}{c_i - b_i} \quad \text{if } c_i \neq b_i \tag{18}$$

$$k_2 = \frac{a_i - b_i}{c_i - b_i} \quad \text{if } c_i \neq b_i \tag{19}$$

and from equations 18 and 19:

$$k_1 + k_2 = 1 \tag{20}$$

or

$$k_1 b_j x^{n-j} + (1 - k_1) c_j x^{n-j} = a_j x^{n-j} \qquad j = 1 \ldots n \tag{21}$$

Thus, the following relationship between the given polynomial $P(x)$ and its two component polynomials $B(x)$ and $C(x)$ are arrived at, as:

$$P(x) = k_1 B(x) + (1 - k_1) C(x) \tag{22}$$

where k_1 is given by equation 18.

As an illustration, consider the following cases:

1. Second-degree polynomials. Let

$$P(x) = x^2 + a_1 x + a_2 \tag{23}$$

be the given polynomial with positive real coefficients and complex zeros. For this simple case, the discriminant is

$$a_1^2 - 4a_2 = 0 \tag{24}$$

and can be represented as a parabola in the 2-dimensional space shown in Fig. 2. Point $G(a_1a_2)$ in Fig. 2 represents the given polynomial (equation 23), and must lie on the left-hand side of the discriminent and in the first quadrant. Draw any straight line from $G(a_1a_2)$ and select points $H(b_1b_2)$ and $F(c_1c_2)$. The points H and F thus will be collinear with G and must be selected to lie on the right-hand side of the discriminant and in the first quadrant.

Draw the vector **OG**, **OH**, and **OF** from the origin to the three points G, H, and F, respectively. Since G, H, and F are collinear, then vectors **FG** and **FH** must have the same direction and their ratio λ is a real number which will be shown later to be k_1.

$$\mathbf{FG} = \lambda \mathbf{FH} \tag{25}$$

As H lies between G and F as shown in Fig. 2, therefore λ is positive real and greater than one. Also it is seen that

$$\mathbf{OF} - \mathbf{OG} = \lambda[\mathbf{OF} - \mathbf{OH}] \tag{26}$$

Solving for **OG**, a relationship is obtained similar to equation 22:

$$\mathbf{OG} = \lambda \mathbf{OH} + (1 - \lambda)\mathbf{OF} \tag{27}$$

Let the termini of the vectors **OG**, **OH**, and **OF** represent respectively the points whose co-ordinates are the coefficients of the polynomials $P(x)$, $B(x)$, and $C(x)$ in the 2-dimensional space, it then can be stated that:

$$P(x) = \lambda B(x) + (1 - \lambda) C(x) \tag{28}$$

where

$$B(x) = x^2 + b_1 x + b_2 \tag{29}$$

and

$$C(x) = x^2 + c_1 x + c_2 \tag{30}$$

It is obvious that $P(x)$, $B(x)$, and $C(x)$ as shown are linearly dependent and that λ is identical with k_1. Since λ is greater than unity, the original polynomial has been resolved into the difference of two polynomials.

However, if the point G is chosen so that it lies between H and F in the collinear condition shown in Fig. 3, then, as before,

$$\mathbf{FG} = \lambda \mathbf{FH} \tag{31}$$

where λ is positive, real, and less than one as can be seen from Fig. 3. Thus the original polynomials become the sum of two polynomials

$$\mathbf{OG} = \lambda \mathbf{OH} + (1 - \lambda)\mathbf{OF} \tag{32}$$

where λ is likewise equal to k_1.

If G is between H and F and is very close to the a_2-axis, then the distance between H and F becomes very large. In the limiting case H would be chosen at the origin, G on the a_2-axis, and F will be the other end of the straight line OGF that terminates in the real-root domain at infinity. Since the results are quite simple, it is no problem to resolve a second-degree polynomial into a sum or difference of two polynomials having real negative zeros.

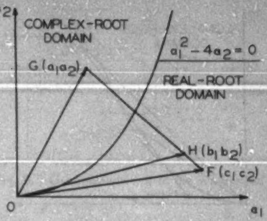

Fig. 2. Resolution of a second-degree polynomial into the difference of two polynomials

2. Third-degree polynomial. Let

$$P(x) = x^3 + a_1 x^2 + a_2 x + a_3 \tag{33}$$

be the given polynomial with positive real coefficients and complex zeros. The discriminant of equation 33 can be represented as a surface in 3-dimensional space. Assuming that G lies in the complex-root domain, a straight line can always be drawn from G that terminates in the positive octant and in the real-root domain. Point H is then selected on the line in the real-root domain. Point F which is also in the real-root domain is obtained by extending the straight line. The procedure followed is then the same as previously outlined. The plot for the boundary is not included for the third degree as it is not a simple surface.

3. Nth degree polynomials. From the foregoing discussion, it can be seen that a polynomial represented by a point in the complex-root domain can always be expressed as the linear combination of two polynomials represented by their point in the real-root domain. However, due to the complexity of the boundary for higher degree polynomials, it may be difficult to have G located between H and F, whereas it is much easier to select F near H and determine the distance between F and H. Thus, the resolution of $P(x)$ is the difference of two polynomials having negative real zeros with k_1 greater than one.

The foregoing method can easily be extended to polynomials having positive real zeros or zeros with positive real parts. This will be sufficient to introduce negative coefficients in the given polynomial. Consider again the following second-degree polynomial:

$$P(x) = x^2 + a_1 x + a_2 \tag{34}$$

where a_1 is a negative real number and a_2 is a positive real number. The point

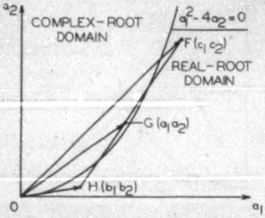

Fig. 3. Resolution of a second-degree polynomial into the sum of two polynomials

$G(a_1a_2)$ as representing equation 34 is shown in Fig. 4. The collinear condition still exists, hence two polynomials are suffiicent. This case can thus be extended to the n-dimensional case, if it is remembered that a straight line can always pass from any point in the complex-root domain to a point in the real-root domain of positive coefficients.

Detailed Procedures for Resolving a Polynomial with Real Coefficients into the Difference of Two Polynomials with Negative Real Zeros

If $B(x)$ and $C(x)$ of equations 10 and 11 are represented by points H and F of equations 13 and 14 in n-dimensional space and lie near to each other, then it can be said that:

$$c_i=\mu_i b_i \qquad i=1, 2, \ldots n \tag{35}$$

Since polynomials $B(x)$ and $C(x)$ are to have negative real zeros, their coefficients are necessary positive numbers. Hence

$$\mu_i>0 \tag{36}$$

Substituting equation 35 in 18 gives

$$k_1=\frac{\mu_i-\dfrac{a_i}{b_i}}{\mu_i-1} \tag{37}$$

$$=\frac{\beta_i\mu_i-1}{(\mu_i-1)\beta_i} \tag{38}$$

where

$$\beta_i=b_i/a_i \qquad i=1, 2, \ldots n \tag{39}$$

and

$$\mu_i\neq 1 \tag{40}$$

As has been shown, $\mu_i\neq 1$, except when $a_i/b_i=1$. In this case $k_1=1$ or the polynomials $P(x)$ and $B(x)$ are identical as will be discussed later.

Therefore there must be constructed a polynomial $B(x)$ which has the same degree as the given polynomial, and whose point $H(b_1b_2 \ldots b_n)$ must lie in the domain common to the positive and real-root domains. After $B(x)$ is obtained, then a value of $\mu_s>0$ must be assumed for a particular set of a_s, b_s, and c_s. k_1 is then determined for this assumed value of μ_s. To simplify this process, Fig. 5 was plotted for β_s against k_1 with μ_s as parameter for the cases of positive value of $\beta_s (s=1 \ldots n)$. Fig. 6 was plotted for the case of negative value of β_s, $(s=1 \ldots n)$ or the given polynomial contains negative coefficients.

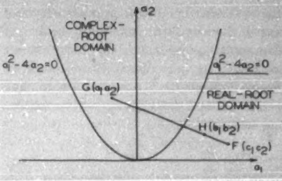

Fig. 4. Resolution of a second-degree polynomial containing negative coefficients

From the discussion, a procedure can be arrived at which can be easily followed in the resolution process. To simplify the procedure, the following is chosen:

$$b_n=c_n=a_n \tag{41}$$

Geometrically, this implies that G, H, and F are all on the straight line perpendicular to the a_n-axis of the n-dimensional space.

1. Construct a polynomial.

$$B(x)=(x+r_1)(x+r_2)\ldots(x+r_n) \tag{42}$$

$$=x^n+b_1x^{n-1}+\ldots+b_{n-1}x+a_n \tag{43}$$

where $r_1r_2 \ldots r_n$ are positive real numbers such that the resulting polynomial, equation 43, will have its coefficients satisfy the following equation:

$$b_i>a_i \qquad i=1\ldots n-1 \tag{44}$$

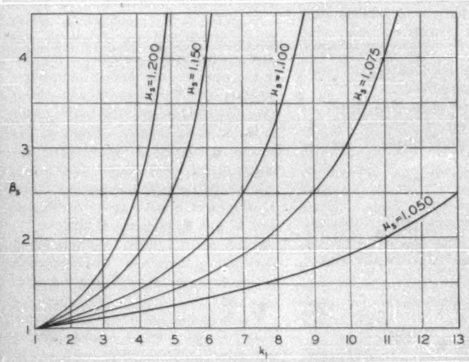

Fig. 5. β_s **versus** k_1 **(positive value of** β_s**)**

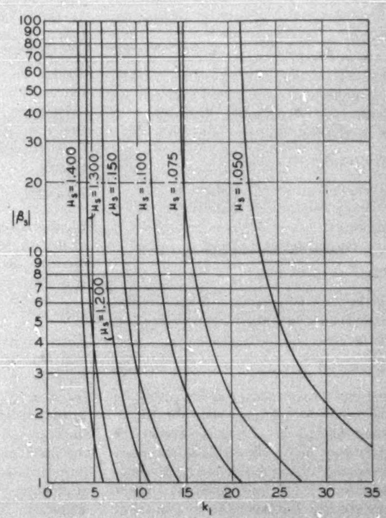

Fig. 6 (right). β_s **versus** k_1 **(negative values of** β_s**)**

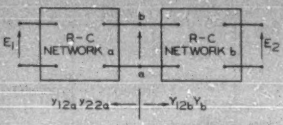

Fig. 7. Two R-C networks in cascade

2. Find β_i from equation 39.

3. Choose one β_i say β_s and assume a value of μ_s. To choose μ_s, Fig. 5 or 6 can be used as a first guess. By the chosen value of β_s, a rough estimate of the relative magnitude of μ_s and k_1. can be obtained. Thus

$$k_1=\frac{\beta_s\mu_s-1}{(\mu_s-1)\beta_s} \tag{45}$$

4. After k_1 is obtained, then μ_j can be found through the relation:

$$\mu_j=\frac{\beta_jk_1-1}{\beta_j(k_1-1)} \qquad \begin{matrix} j=1\dots n-1 \\ j\neq s \end{matrix} \tag{46}$$

5. The coefficients of $C(x)$ can be obtained by using the relation

$$c_i=\mu_ib_i \qquad i=1\dots n-1 \tag{47}$$

6. Test $C(x)$ by the real-root criterion as outlined in Appendix I. If it is not satisfied, reduce μ_s and proceed again.

The Uppermost Bound of the Minimum Number of Polynomial Whose Sum Is Equal to a Given Polynomial

The foregoing method gives a powerful tool for resolving a polynomial into polynomials having negative real zeros. In general, it has been shown[10] that the minimum number t of the components of a polynomial with positive real coefficients of nth degree is between the lowest bound of two and the uppermost bound which is the least integer greater than $n/2$ or

$$\begin{aligned} 2\leqslant t &\leqslant\frac{n+1}{2} && \text{if } n \text{ is odd} \\ &\leqslant\frac{n}{2}+1 && \text{if } n \text{ is even} \end{aligned} \tag{48}$$

To show that the uppermost bound is that given in equation 48 consider the polynomial having positive real coefficients as:

$$P(x)=x^n+\alpha_1x^{n-1}+\delta_2x^{n-2}+\alpha_3x^{n-3}+\delta_4x^{n-4}+\dots+\delta_n \tag{49}$$

where n is even and α's are very small compared with δ's or

$$\delta_{i+1}>>\alpha_i \qquad i=1, 2, \dots n-1 \tag{50}$$

In case n is odd, the real zero can always be factored out and a polynomial of even degree obtained.

It is always possible to write $P(x)$ as

$$P(x)=Q_1(x)+\sum_{p=1}^{n/2} C_pR_p(x) \tag{51}$$

where $Q_1(x)$ is an nth degree polynomial with all zeros real and negative and $C_p>0$. Since α_1 is very small and the coefficients of all $R_p(x)$, $p=1 \dots n/2$, are all positive real, therefore the coefficients of $Q_1(x)$ must be all very small. This implies that the zeros of $Q_1(x)$ are very small.[7] Let $Q_1(x)$ be expressed as:

$$Q_1(x)=x^n+d_1x^{n-1}+d_2x^{n-2}+\dots+d_n \tag{52}$$

and let

$$d_1=\alpha_1 \tag{53}$$

and

$$d_j\leqq\alpha_j \qquad j=2, 4, \dots n \tag{54}$$

This can only be obtained by choosing

$$\epsilon_i>0 \qquad i=1, 2, \dots n \tag{55}$$

small enough such that

$$\epsilon_1+\epsilon_2+\dots+\epsilon_{n-1}=\epsilon_n<\alpha_1 \tag{56}$$

then

$$Q_1(x)=(x+\epsilon_1)(x+\epsilon_2)\dots[x+(\alpha_1-\epsilon_n)] \tag{57}$$

has negative real zeros.

Since $\alpha_1=d_1$, then $P(x)-Q_1(x)=\sum_{p=1}^{n/2}C_p R_p(x)$ contains no terms of degree higher than $n-2$. The degree has thus been reduced by two in the resolution. The degree cannot be reduced more than two at a time, since the next coefficients δ_2 of the given polynomial is much larger than α_1, hence $Q_1(x)$ cannot be obtained to carry off the first three terms of $P(x)$ without sacrificing the condition of its negative real zeros.

By repeating this process, at each step a new polynomial is obtained of two degrees lower than before. Thus the minimum number is $n/2+1$.

However, a polynomial could always be resolved simply by grouping the successive terms two at a time, as:

$$P(x)=(x+a_1x^{n-1})+(a_2x^{n-2}+a_3x^{n-3})+\dots+a_n \tag{58}$$

The number of resolution is $(n+1)/2$ if n is odd, and $n/2+1$ if n is even. We do not want to resort to this kind of resolution, as better results may be obtained by other means, unless the given polynomial is of the type mentioned in equation 49. Appendix II gives the theorem that defines the condition under which the given polynomial can only have this minimum number of components.

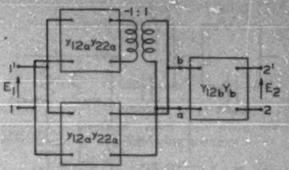

Fig. 8. Generalized form of the synthesized network

Example

The synthesis presented is based on the foregoing method of resolving the numerator polynomial into the difference of two component polynomials containing negative real zeros. The zero-cancellation device and the application of Norton's network theorem as derived by Weinberg,[5] together with the zero-shifting method as derived by Guillemin[8] are used in the example.

From equations 2 and 4 the transfer function is

$$H(p)=K\frac{P_1(p)P_2(p)}{Q(p)} \tag{59}$$

Introduce

$$W(p)=W_1(p)xW_2(p) \tag{60}$$

such that

$$H(p)=K\frac{\left(\frac{P_1(p)}{W_1(p)}\right)\left(\frac{P_2(p)}{W_2(p)}\right)}{\frac{Q(p)}{W_1(p)W_2(p)}} \tag{61}$$

The denominator of equation 61 can be partial-fractioned as

$$=K\frac{\left(\frac{P_1(p)}{W_1(p)}\right)\left(\frac{P_2(p)}{W_2(p)}\right)}{\frac{Q_1(p)}{W_1(p)}+\frac{Q_2(p)}{W_2(p)}} \tag{62}$$

$$=K\frac{(y_{12a}(p))(Y_{12b}(p))}{y_{22a}(p)+Y_b(p)} \tag{63}$$

where $y_{12a}(p)$ and $y_{22a}(p)$ are the short-circuit transfer and driving point admittances of network a and $Y_{12b}(p)$ and $Y_b(p)$ are the short-circuit transfer and driving point admittances of network b as shown in Fig. 7. Network b is the termination ladder and network a contains the parallel combination of the two R-C ladders and an ideal transformer.

Now resolve $P_1(p)$ by the method outlined before:

$$P_1(p)=k_1P_1^{(1)}(p)+k_2P_1^{(2)}(p) \tag{64}$$

where $k_2=1-k_1$. Then equation 63 becomes

$$H(p)=\frac{[k_1y_{12a}^{(1)}+k_2y_{12a}^{(2)}]\,Y_{12b}}{y_{22a}+Y_b} \tag{65}$$

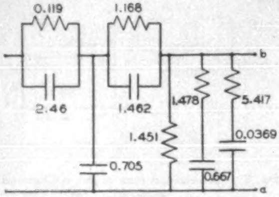

Fig. 9. Example: first parallel ladder

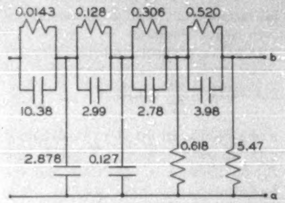

Fig. 10. Example: second parallel ladder

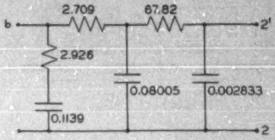

Fig. 11. Example: termination ladder

The factoring of $W(p)$ into $W_1(p)$ and $W_2(p)$ must be made such that $W_1(p)$ is one degree lower than $P_1^{(1)}(p)$ or $P_1^{(2)}(p)$ in order to be physically realizable.[4,8,11]

To reduce the number of elements, the process of resolving $P_1(p)$ and the factoring of $W(p)$ should be co-ordinated so that zero-cancellation may occur. This may be done by factoring the $W(p)$ in such a way that the component $W_1(p)$ contains some of the zeros of $P_1^{(1)}(p)$ or $P_1^{(2)}(p)$ and the component $W_2(p)$ contains some of the zeros of $P_2(p)$.

From equation 63, $y_{12a}^{(1)}y_{22a}$ and $y_{12a}^{(2)}y_{22a}$ are each synthesized from right left into two R-C ladders by the zero-shifting method. They are then paralleled to through an ideal transformer of $-1:1$ ratio as shown in Fig. 8 after the proper gain adjustment. To adjust the gain, the following can be done:

There is given

$$y_{12a}=k_1y_{12a}^{(1)}+k_2y_{12a}^{(2)} \tag{66}$$

After the synthesis,

$$(A_1y_{12a}^{(1)}+A_2y_{12a}^{(2)}) \tag{67}$$

A_2 here is assumed to be negative as this includes the ideal transformer of $-1:1$ ratio and $k_2=1-k_1$. In order to bring the y_{22a} of the two ladders to the same value, the gain of y_{12a} must be adjusted. Hence, write the given y_{12a} as

$$y_{12a}=\frac{k_1}{A_1}[A_1y_{12a}^{(1)}]+\frac{k_2}{A_2}[A_2y_{12a}^{(2)}] \tag{68}$$

Therefore the over-all y_{12a} of the two ladders and the ideal transformer is changed by a factor of

$$G=\frac{k_1}{A_1}+\frac{k_2}{A_2} \tag{69}$$

Then each component $y_{12a}^{(1)}$ of equation 66 will be multiplied by the corresponding factor of

$$\frac{k_i}{A_iG} \qquad i=1,\ 2 \tag{70}$$

Now consider the following example.

Given the transfer function:

$$H(p)=K\frac{(p+3)(p^4-2p^3-p^2+2p+10)}{(p+0.5)(p+1.5)(p+2.5)(p+3.5)(p+4.5)(p+5.5)(p+6.5)}$$

it is required to synthesize $H(p)$ into two parallel R-C ladders and ideal transformer with termination ladder within a constant multiplier. The procedure can be done by the following steps.

1. The numerator can be represented:

$$P_1(p)=p^4-2p^3-p^2+2p+10$$
$$P_2(p)=p+3$$

where $P_1(p)$ and $P_2(p)$ are defined in equation 4.

2. By use of the resolution procedures as outlined before, $P_1(p)$ can be resolved as follows:

(*a*) Construct $P_1^{(1)}(p)=(p+0.5858)(p+1)(p+3.4142)(p+5)$ $=p^4+10p^3+31p^2+32p+10$

(*b*) $\beta_1=-5,\ \beta_2=-31,\ \beta_3=16$

(*c*) Choose $\beta_3=\beta_1=-5$. From Fig. 6, choose $\mu_3=1.1,\ k_1=13,\ \mu_3=1.075,\ k_1=16$;

Use

$$\mu_3=1.1,\ k_1=13$$

Compute

(*d*) $\mu_2=1.086,\ \mu_3=1.078$

(*e*) $c_1=11,\ c_2=33.67,\ c_3=34.50$

(*f*) $P_1^{(2)}(p)=p^4+11p^3+33.67p^2+34.50p+10$;

$P_1^{(2)}(p)$ in item (*f*) satisfies the reality criterion of equation 71. The following equation is thus obtained:

$$\begin{aligned}P_1(p)&=13(p^4+10p^3+31p^2+32p+10)-12(p^4+11p^3+33.667p^2+34.50p+10)\\&=13(p+0.5858)(p+1)(p+3.4142)(p+5)-12(p+0.4830)(p+1.175)(p+2.619)(p+6.723)\end{aligned}$$

3. Choose $W(p)$

$$W(p)=(p+1)(p+2)(p+3)(p+4)(p+5)(p+6)$$

As can be seen, $W(p)$ has one zero-cancellation with $P_2(p)$ and two zero-cancellations with $P_1^{(1)}(p)$. Hence, factoring $W(p)$ into $W_1(p)$ and $W_2(p)$ results in the following:

$$W_1(p)=(p+1)(p+2)(p+5)$$
$$W_2(p)=(p+3)(p+4)(p+6)$$

4. All the component functions can thus be written according to equations, 64, 63, and 61 as:

$$y_{12a}^{(1)}=\frac{P_1^{(1)}(p)}{W_1(p)}=\frac{(p+0.5858)(p+3.4142)}{(p+2)}$$

$$y_{12a}^{(2)}=\frac{P_1^{(2)}(p)}{W_1(p)}=$$

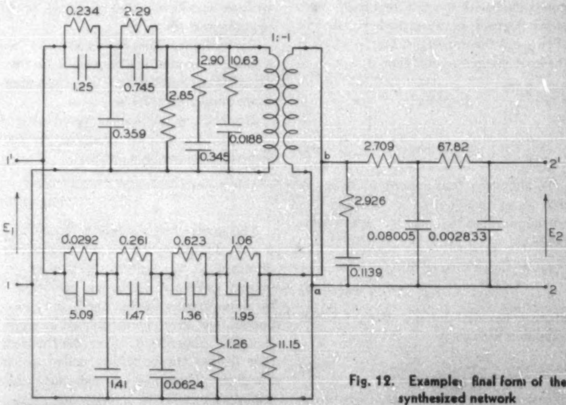

Fig. 12. Example: final form of the synthesized network

$$\frac{(p+0.4830)(p+1.175)(p+2.619)(p+6.723)}{(p+1)(p+2)(p+5)}$$

$$y_{21a}=\frac{Q_1(p)}{W_1(p)}=(p+1.4663)+\frac{0.6768p}{p+1}+\frac{0.4613p}{p+2}+\frac{0.1846p}{p+5}$$

$$y_{22a}=\frac{p^4+10.789p^3+36.790p^2+44.341p+14.663}{p^3+8p^2+17p+10}$$

$$Y_{12b}=\frac{P_2(p)}{W_2(p)}=\frac{1}{(p+4)(p+6)}$$

$$Y_b=\frac{Q_2(p)}{W_2(p)}=\frac{0.3418p}{p+3}+\frac{0.2564p}{p+4}+\frac{0.1128p}{p+6}$$

5. Synthesize network a from right to left. First synthesize $y_{12a}^{(1)}$ and y_{22a} by the zero-shifting method into an R-C ladder. The poles at $p=-1$ and $p=-5$ must be removed first from y_{22a} as parallel branches and the resulting R-C ladder is shown in Fig. 9. Now synthesize $y_{12a}^{(2)}$ and y_{22a} and the resulting R-C ladder is shown in Fig. 10.

6. Synthesize the Y_{12b} and Y_b as the termination ladder of network b from left to right. The shunt branch $\frac{0.3418p}{p+3}$ is first removed and the remaining terms can be synthesized by the method of continued fractions.[4] The resulting ladder is shown in Fig. 11.

7. Adjust the gain of the two ladders of network a and then parallel them through the ideal transformer. As $k_1=13$ and $k_2=-12$, and, from the synthesized ladders, $A_1=0.7764$ and $A_2=-0.7446$, thus:

$$G=\frac{13}{0.7764}+\frac{12}{0.7746}=32.86$$

Hence, for the first ladder in network a, each R should be divided by $A_1G_1/k_1=0.510$ and each C should be multiplied by 0.510. For the second ladder in network a each R should be divided by $k_2/A_2G_2=0.491$, and each C should be multiplied by 0.491.

The final network is then shown in Fig. 12. It has a total of only 28 elements.

Appendix I Criterion for the Negative Reality of Zeros of a Polynomial[10]

Theorem I

If $P(x)=a_0x^n+a_1x^{n-1}+a_2x^{n-2}+\ldots+a_n$ is a polynomial with all coefficients real and positive, then a necessary and sufficient condition that the zeros of the polynomial be real, distinct, and negative is that

$$S_p>0 \qquad p=1, 2, \ldots n \tag{71}$$

where S_1, S_2, $\ldots S_p$, $\ldots S_n$ are the first, third, $\ldots$ and $(2n-1)$th principal minors (blocked off by lines) in the array

$$\left\|\begin{array}{cccccc} a_1 & 2a_2 & 3a_3 & 4a_4 & 5a_5 & 6a_6\ldots \\ a_0 & a_1 & a_2 & a_3 & a_4 & a_5\ \ldots \\ 0 & a_1 & 2a_2 & 3a_3 & 4a_4 & 5a_5\ldots \\ 0 & a_0 & a_1 & a_2 & a_3 & a_4\ \ldots \\ 0 & 0 & a_1 & 2a_2 & 3a_3 & 4a_4\ldots \\ 0 & 0 & a_0 & a_1 & a_2 & a_3\ \ldots \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ \multicolumn{6}{l}{a_j=0 \text{ if } j>n} \end{array}\right\| \tag{72}$$

The zeros of $P(x)$ must be distinct, hence if there are repeated zeros present, they should be factored out first by the Euclidean algorithm of the H.C.F. process between $P(x)$ and $P'(x)$.[7]

Appendix II Condition for Uppermost Bound of Minimum Number of Components in the Resolution of a Polynomial[10]

Theorem II

If $m(n)$ be the least integer such that any nth degree polynomial with positive coefficients can be expressed as a linear combination with positive coefficients of at most $m(n)$ polynomials, each of which has all its zeros negative, then $m(n)$ is the least number greater than $n/2$.

The relative magnitude of α's and δ's of equation 49 that should be attained when the minimum number of components in $n/2+1$ will be

$$P(x)=x^n+a_1x^{n-1}+\left\{\binom{n}{2}\binom{na_1}{2}^2+k_2\right\}x^{n-2}+a_3x^{n-3}+\left[\binom{n}{4}\left\{\binom{na_1}{2}^4+a_2\left[\frac{(n-2)\binom{n}{2}a_2}{2K_2}\right]^2\right\}+k_4\right]x^{n-4}+a_5x^{n-5}+\ldots \tag{73}$$

where a_i is the coefficient of x^{n-i} in $P(x)$ and is determined after $a_1\ldots a_{i-1}$ are determined in the following manner

$$a_i=\begin{cases}\text{arbitrary} & \text{if } i \text{ is odd}\\ \binom{n}{i}\sum_{j=0}^{1/2}a_{2j}\times\left[\frac{(n-2j)\binom{n}{2j}a_{2j}+1}{2k_{2j}}\right]^{i-2j}+k_i & \text{if } i \text{ is even}\end{cases}$$

$$a_0=k_0=1 \tag{74}$$

and k_i is an arbitrary positive number which occurs in the formula for a_i.

Discussion

I. Horowitz (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): Aside from the question of the desirability of ideal transformers in R-C networks, the basic problem considered by the authors is: How can a polynomial $P(p)$ be written as the difference of two polynomials, each with negative real zeros only. The following procedure suffices:

1. Divide $P(p)$ by $D(p)=(p+a_1)(p+a_2)\ldots(p+a_n)$, where n is at least the degree of P and the a_j's are real, positive, and distinct.

2. Make a partial fraction expansion of $P(p)/D(p)$. All residues are real. Collect all positive residue terms as F_1, and negative residue terms as $-F_2$.

$$\frac{P(p)}{D(p)}=F_1(p)-F_2(p)$$

3. Multiply both sides of this equation by $D(p)$, giving $P(p)=D(p)F_1(p)-D(p)F_2(p)$.

DF_1 and DF_2 are each polynomials with negative real zeros only. F_1 and F_2 are each R-C driving point impedances, hence have only negative real zeros. $D(p)$ includes factors cancelling all poles of F_1 and F_2. This problem arose in the design of active R-C networks.

Automatic Network Analysis with a Digital Computation System

S. Y. WONG
ASSOCIATE MEMBER AIEE

M. KOCHEN
NONMEMBER AIEE

THE ANALYSIS of large electric and fluid networks is of great importance in engineering. Hand computation is generally impractical when the network is large. The network analyzer is currently the only practical means for solving such problems.

Very few network analyzers are equipped with programmed input-output systems, so that much time is spent in the setting up of problems on them. Attempts to overcome some of the limitations of network analyzers by the use of digital computing machines for network calculations have been made.[1] The methods so far developed are intended mostly for small accounting machines of the punched-card variety. However, much manipulation of the problem is involved before it reaches the computing machine. Hence, digital methods have gained little favor among engineers in the field.

Mathematical methods are available to obtain solutions directly from the circuit diagram by inspection of the networks according to definite rules.[2,3] The necessity to scan the input repeatedly makes these methods ill-suited to small accounting machines. With the advent of large-scale high-speed electronic digital computers, the digital solution of network problems becomes practicable.

The Digital Computing System

The most important aspect of a digital computing system is that once a program for a particular network has been constructed, it can be stored in coded form suitable for machine input and for later use in analysis of modifications of the network. A master library serves to ensure that every program developed by any one digital computing system is available to every other interested system. If several such systems operate over a long period, it will be highly probable that a program will be available to handle most commonly encountered network engineering problems.

To determine whether a digital computing system can be set up with the maximum convenience to the user, a sample system was tested on the Institute for Advanced Study computer. One basic machine program for d-c networks was made, and several variations of this were used to solve different types of problems. The mathematical basis of this program and its range of applicability will be discussed, although any number of techniques for solving systems of linear equations, some preferable to the one employed here, could be substituted. The significant aspect of this paper is the procedure of the automatic formulation of the problem from a circuit diagram, rather than the details of solving the mesh and loop equations.

It is supposed that the problem originator provides the following information when he submits his problem to a computing system:

1. A circuit diagram with the resistances or admittances and the electromotive forces (emf) in every branch.
2. The unknown quantities to be computed; i.e. the currents in one or more branches, the potentials at certain nodes.

The following steps characterize the procedure within the computing system which was tested:

1. If the branches and/or junctions are not already numbered by the problem originator when he submits a circuit diagram, this task is done by the first member of the computing system who handles the problem. An algebraic description (an incidence matrix) of the circuit diagram is then prepared.
2. Transformation codes then convert these data into a form which is suitable for machine computation with one of the available coded programs. This can generally be accomplished in a matter of seconds.
3. The complete information about the circuit being thus stored in the machine, the general-purpose program to solve the network is also read into the machine, and the desired quantities are calculated and transformed back into a form which permits their ready interpretation.
4. These answers are then automatically printed in tabular form and/or entered back upon the circuit diagram.
5. The problem may be rerun to duplicate the answers, or these may be checked by comparison with certain known quantities.
6. The coded input information and the possible program variations are filed and stored (on cards, tape, etc.) in the system's library for possible repeat runs. It takes a matter of minutes to set up the machine for a run.

Network Topology

An electric network is a linear graph where the conductors are edges or branches and the junctions are vertices or nodes. Let the N nodes be numbered 0, $\ldots$, i, $\ldots$, N-1 in an arbitrary manner. In the sample problem which was solved, the following parameters were associated with the branch connecting the ith to the jth node.

Let Z_{ij} be the resistance, $a_{ij}=\dfrac{1}{Z_{ij}}$ be the admittance of that branch, and e be the absolute value of the emf of a battery in such a branch, where i is taken to be the number of the node connected to the negative terminal of the battery.

$$e_{ij}=\begin{array}{l} +e \text{ if } i=\text{Min}\,(i,j) \\ -e \text{ if } i=\text{Max}\,(i,j) \end{array} \quad \text{by convention}$$

It is evident that $e_{ij}=-e_{ji}$ and that $a_{ij}=a_{ji}$. By convention $e_{ii}\equiv 0$ and $a_{ii}\equiv 1$. v_i is the potential at the ith node relative to ground, which is taken as 0.

In order to represent the network topology with minimum data for the purpose of conserving memory space (eliminating the redundancy of writing the usual incidence matrix in which every branch appears twice) the following scheme of numbering the nodes was proposed: Suppose that the first i nodes have been numbered 0, ..., i-1 according to this scheme, and consider the ith node. Call the set of nodes which are connected to the ith node by a single branch, G_i. Include in G_i only those node numbers which are greater than i. It is clear that every combination $(i,i')\ i,i'=0,\ldots,N-1,\ i\neq i'$ will occur once and only once. Thus, the sequence of integers, grouped according to $G_0, G_1, \ldots, G_{N'}$, $N'\leq N-1$, specifies the network topology. Letting n be the

number of branches, there are n integers, $\zeta_1, \ldots, \zeta_t, \ldots, \zeta_n$, representing destination nodes, in the foregoing sequence. The groups $G_0, G_1, \ldots, G_{N-1}$ can be stored in a sequential fashion in the memory. Since the integer t of G_t does not appear explicitly in the group G_t it is necessary to put this integer t ahead of the integers in G_t. It is convenient to associate a binary variable, η_t, called the nodal index, to every integer in this sequence. $\eta_t=1$ if the integer corresponds to t of G_t otherwise. The reason for requiring the number t to appear explicitly is that sometimes G_t may contain no integers, as in the case of a node boxed in by nodes of lower numbers.

It is then possible to record all the information necessary to specify the network topology in $(n+N)(\log_2(N)+1)$ binary digits, where (N) is the smallest power of 2 which is not less than N. The parameters a_{ij}, and e_{ij} are written next to every branch, and if these are known to an accuracy of A and $E+1$ bits, respectively, then the entire network can be described by a table which requires $(n+N)(A+E+2+\log_2(N))$ bits to store. To determine the incident node (with lower node number) for the tth branch, it is merely necessary to examine the number in G_t whose $\eta_t=1$. The destination node (with higher node number) is given by ζ_t. If $v_0, \ldots, v_{N-1}$ are stored in machine addresses numbered 0 to $N-1$, it is very convenient to let $i, \zeta_t=0, \ldots, N-1$ represent these addresses.

If a node has only two branches connected to it, the pair of branches represents two conductors in series, and such a node can be eliminated. If m $(m \geq 2)$ branches connect the same pair of nodes (i.e., the conductors are in parallel), artificial nodes are assigned to m-1 of of these branches. Each such conductor is thus divided into two conductors in series, and the conductances and emf are conveniently distributed to the parts.

Table I is an example of how the circuit in Fig. 1 can be tabulated. At the expense of additional storage space, the lines could also be numbered independently, making the treatment of lines in parallel somewhat simpler.

Method of Solution

An iterative procedure based on a theorem first proved by Maxwell[4] is used to obtain the solution of the d-c network as a set of potentials at the various junctions. An initial guess is provided by the program but intelligent guesses can be substituted if desired. Usually the time required to prepare a set of intelligent guesses is not justified because the difference in machine computing time is only a few minutes. The solution is predetermined whenever the potentials of two or more junctions of the network are given and fixed. The power dissipated by the system is a minimum when the set of potentials corresponds to the exact solution. The program uses the method of steepest descent to approach the exact solution. A simplified flow diagram of this program is shown in Fig. 2.

The Institute for Advanced Study machine has an internal high-speed memory of 1,024 words and a slower magnetic drum memory of 2,048 words. Input and output are through punched cards. The program is designed for networks of less than 256 lines and 128 junctions. All the circuit information and computing program can be accommodated in the internal memory. For larger networks, the magnetic drum has to be used with great loss in speed. The solution is punched on cards and a tabulating machine is used to present it to the problem originator in printed form.

A simple Wheatstone bridge, a plane potential problem, and a temperature distribution problem were solved by this method. The computing time ranges from 2 minutes to less than 15 minutes.

Fig. 3. Wheatstone bridge to illustrate numbering scheme

The mathematical details of the program appear in the appendixes. By attaching a variation to the program, a system for solving short-circuit currents was tried. A typical distribution network was analyzed both by d-c network analyzer and by this digital computing system. The two results are shown in Fig. 3. In all instances, the number above a line indicates the result by analyzer and the number underneath a line indicates the result by the digital system. A solid separation line associated with a branch terminating on a given bus indicates the contribution of short-circuit current by that branch when the given bus is short-circuited to ground. Dotted lines between two numbers indicate the total current flowing into the short circuit. The generator junctions are fixed at unity voltage while the grounded bus is fixed at zero. The set of potentials of the solution is of no interest and is therefore not produced in the output. Instead, the currents involved at the short-circuited bus are derived from this set of voltages, and these are printed out. The program then moves the short circuit to another bus and repeats the process until all busses of interest are short-circuited and computed.

Conclusions

The use of digital computers, when developed into a system, is a practical way of solving complex network problems. It is demonstrated by the foregoing procedure that high-speed digital computers can be programmed such that the problem originator needs little or no information about the computing methods employed. Changes in a circuit which have previously been analyzed are readily effected with very little setup time. With the increasing adoption of large computers for accounting purposes, the addition of a network computation system involves only the creation of a group of program designers skilled in network problems. A person accustomed to analyzer methods need experience no loss in convenience when using digital methods instead. It is suggested that a floating-point computing machine with a larger internal memory be used because with a fixed-point machine, scaling difficulties seriously limit the accuracy.

Vol. Pt. 1 1956

Appendix I. Solution of Network Equations by Minimization of Power

Let $V_0, \ldots, V_k$, $k \geq 1$, be the known potentials, which are to remain unchanged throughout the entire calculation. Let $V_{k+1}, \ldots, V_{N-1}$ be the desired potential, for which intelligent or standard guesses are initially provided. Let I_{ij} be the correct current in the branch ij of a linear resistive network. $R_{ij} = \frac{1}{a_{ij}}$ is the resistance in that branch. Let V_i be the correct (yet unknown) potential at the ith node, including external emf's, so that $I_{ij} = a_{ij}(V_i - V_j)$. Next, let W_i be an approximation to V_i, and T_{ij} be the associated approximation to I_{ij}, so that $T_{ij} = a_{ij}(W_i - W_j)$ and $T_{ij} = I_{ij} + \epsilon_{ij}$. Let

$$P^* = \sum_i \sum_j R_{ij} T_{ij}^2 = \sum_{i,j} a_{ij}(W_i - W_j)^2$$

summed over the relevant values of i and j.

Theorem: P^* is minimum if and only if $T_{ij} = I_{ij}$, all i, j.

Proof: When P^* is minimum, W_i satisfies:

$$0 = \frac{\partial P^*}{\partial W_i} = 2\sum_j a_{ij}(W_i - W_j) = \sum_j T_{ij},$$

all i.

Since I_{ij} and T_{ij} are currents, they must satisfy Kirchoff's first law (the equation of continuity),

$$\sum_j I_{ij} = 0, \quad \sum T_{ij} = 0 \text{ for all } i$$

so that

$$\sum_j \epsilon_{ij} = \sum_j (T_{ij} - I_{ij}) = \sum_j T_{ij} - \sum_j I_{ij} = 0$$

also.

Now,

$$\begin{aligned} P^* &= \sum_{i,j} R_{ij}(I_{ij} + \epsilon_{ij})^2 \\ &= \sum_{i,j} R_{ij}(I_{ij}^2 + 2I_{ij}\epsilon_{ij} + \epsilon_{ij}^2) \\ &= \sum_{i,j} I_{ij}^2 R_{ij} + 2\sum_{i,j}(V_i - V_j)\epsilon_{ij} + \\ &\qquad \sum_{i,j} R_{ij}\epsilon_{ij}^2 \end{aligned}$$

But

$$\begin{aligned} \sum_{i,j}(V_i - V_j)\epsilon_{ij} &= \sum_i V_i \sum_j \epsilon_{ij} - \\ &\qquad \sum_j V_j \sum_i \epsilon_{ij} = \\ &\sum_i V_i \sum_j \epsilon_{ij} + \\ &\qquad \sum_j V_j \sum_i \epsilon_{ji} = 0 \end{aligned}$$

Hence

$$P^* = \sum_{i,j}(I_{ij}^2 R_{ij} + R_{ij}\epsilon_{ij}^2)$$

$R_{ij} > 0$ whenever I_{ij} is defined. Consequently, P^* is least when and only when ϵ_{ij} in all the branches where $R_{ij} > 0$ is 0. The minimum power is the power actually dissipated in heat, $\sum_{i,j} I_{ij}^2 R_{ij}$, in terms of the correct currents.

Appendix II. Numerical Algorithm to Compute Solution

Although several efficient methods[5,6] of solving large systems of linear algebraic equations have been programmed for digital computers, it was felt desirable to use the method of steepest descent for purposes of simplicity in testing the performance of the proposed computing system. Whereas the former methods obtain the "exact" solutions in a finite number of steps by manipulating the matrix elements, the method of steepest descent is an iterative procedure, which in this case has the advantage of not requiring the storage of all the matrix elements. Since the method of steepest descent, although well known, is not too readily available in the engineering literature, it is of interest to present a derivation (based on a lecture by H. H. Goldstine[7]) and a description of its use here.

P, regarded as a function of $V_k, \ldots, V_{N-1}$, this $(N-k)$-tuplet being henceforth abbreviated as (a vector) $\mathbf{V}$, is a continuous, bounded, and positive definite function of these variables. These prerequisites permit the determination of $\mathbf{V}$ so as to make P minimum by the method of steepest descent.

Let $\mathbf{V}^0$ be an initial guess, and $\Delta\mathbf{V}$ a correction to it. It is desired to find $\Delta\mathbf{V}$ so as to minimize $P(\mathbf{V}^0 + \Delta\mathbf{V})$, or equivalently, $P(\mathbf{V}^0 + \Delta\mathbf{V}) - P(\mathbf{V}^0)$. Expand $P(\mathbf{V}^0 + \Delta\mathbf{V})$ in a Taylor series about $\mathbf{V}^0$

$$P(\mathbf{V}^0 + \Delta\mathbf{V}) = \sum_{m=0}^{\infty} \frac{1}{m!}(\Delta\mathbf{V} \cdot \text{grad})^m P(\mathbf{V}^0)$$

and, neglecting terms of order higher than the second,

$$P(\mathbf{V}^0 + \Delta\mathbf{V}) - P(\mathbf{V}^0) \doteq \Delta\mathbf{V} \text{ grad } P(\mathbf{V}^0) + 1/2(\Delta\mathbf{V} \cdot \text{grad})^2 P(\mathbf{V}^0)$$

To make the foregoing expression as negative as possible, choose $\Delta\mathbf{V}$ in the direction of the gradient,

$$\Delta\mathbf{V} = -t \text{ grad } P(\mathbf{V}^0)$$

t is a scalar to be determined so as to make

$$\frac{d}{dt}[P(\mathbf{V}^0 + \Delta\mathbf{V}) - P(\mathbf{V}^0)] = 0 =$$

$$\frac{d}{dt}\left\{-t \text{ grad}^2 P(\mathbf{V}^0) + \frac{t^2}{2}(\text{grad } P(\mathbf{V}^0) \cdot \text{grad})^2 P(\mathbf{V}^0)\right\} =$$

$$-\text{grad}^2 P(\mathbf{V}^0) + t\,(\text{grad } P(\mathbf{V}^0) \cdot \text{grad})^2 P(\mathbf{V}^0)$$

Solving for $\Delta\mathbf{V}$,

$$\Delta\mathbf{V} = -\left[\frac{\text{grad}^2 P(\mathbf{V}^0)}{(\text{grad } P(\mathbf{V}^0) \text{ grad})^2 P(\mathbf{V}^0)}\right] \text{grad } P(\mathbf{V}^0)$$

and the ith component of $\Delta\mathbf{V}^h$, $\Delta V_i^h \doteq -P_i^h S^h / D^h$. Because the Taylor series was truncated after two terms, the foregoing expression is only a first approximation to $\Delta\mathbf{V}$. It will be called $\Delta\mathbf{V}^0$. A second approximation may be obtained by repeating the entire calculation using $\mathbf{V}^1$ in place of $\mathbf{V}^0$; where $\mathbf{V}^1 = \mathbf{V}^0 + \Delta\mathbf{V}^0$.

The general inductive step is

$$V_i^{h+1} = V_i^h + \Delta V_i^h$$

The foregoing derivation for the general case for any P satisfying the stated conditions may be simplified if P represents the power in an electric network.

Introducing the abbreviations

$$P_i^h \equiv \frac{\partial P}{\partial V_i} = 2\sum_{j=0}^{N-1} a_{ij}(V_i^h - V_j^h + e_{ij}) - \qquad i = k+1, \ldots N-1,\ h = 0, 1, 2 \ldots$$

$$S^h \equiv \sum_{i=k+1}^{N-1} (P_i^h)^2$$

$$D^h \equiv \sum_{i,j} \frac{\partial P}{\partial V_i} \frac{\partial P}{\partial V_j} \frac{\partial^2 P}{\partial V_i \partial V_j} =$$

$$2\sum_{i=k+1}^{N-1}\left[\sum_{j=i+1}^{N-1} a_{ij}(P_i^h - P_j^h)^2 + \sum_{j=0}^{k} a_{ij}(P_i^h)^2\right]$$

$$t^h = -\frac{S^h}{D^h}$$

Then,

$$\Delta\mathbf{V}^h = -\frac{S^h}{D^h} \text{ grad } P(\mathbf{V})\big|_{\mathbf{V} = \mathbf{V}^h}$$

To see that under the afore-mentioned hypothesis, the successive approximations, $\Delta\mathbf{V}^0$, $\Delta\mathbf{V}^1$, ... do converge to $\Delta\mathbf{V}$, substitute for $\Delta\mathbf{V}^h$

$$\begin{aligned} P(\mathbf{V}^{h+1}) - P(\mathbf{V}^h) &= -\frac{S^h}{D^h} \text{grad}^2 P(\mathbf{V}^h) + \\ &\quad 1/2\left(-\frac{S^h}{D^h}(\text{grad}P \cdot \text{grad})^2 P(\mathbf{V}^h)\right) = \\ &\quad -\frac{S^h}{D^h} S^h + 1/2\frac{(S^h)^2}{D^h} = -\frac{(S^h)^2}{2D^h} \end{aligned}$$

Since P is positive definite, $D>0$ and the foregoing expression is nonpositive.

Discussion

G. W. Bills (North American Aviation, Inc., Downey, Calif.): To read such a clear and orderly paper as this is pleasing. There is little doubt that for most cases the solution of load flow and short-circuit problems can best be carried out by an iteration of nodal equations.

At the Bonneville Power Administration we used the steepest descent method initially in the solution of load flow problems, but Gordon Smith of the Administration finally perfected a Gauss-Seidel technique which has proved far simpler and converges very well. A similar technique was also employed by the Institute of Numerical Analysis at Los Angeles where the same problem was worked on.

It also appears probable that acceleration techniques for decreasing the number of iterations when converging to a solution will be perfected in the near future, although this may be unnecessary with such high-speed computers as the *IBM 704*.

Here at North American Aviation we hope to set up a general program on the *IBM 704*, which is to be in operation this year, for the solution of all types of power system problems. We feel certain that no network analyzer in existence can compete timewise with such a computer once a general program is achieved.

The short-circuit current problem is a good example of the use of a digital computer to eliminate such tedious tasks as recording short-circuit values from a d-c board. In the program contemplated here the effects of mutual couplings between lines is also to be included.

Have the authors attempted the application of network topology along with digital computers to system problems?

I feel that this paper is a definite contribution to those engaged in network analysis. It appears that these digital methods can easily be extended to more difficult network problems such as the synthesis of networks.

S. Y. Wong and **M. Kochen:** The authors have not seriously looked into system problems other than the one described. However, there is some reason to believe that the proposed digital computing system with some possible variation in the choice of the mathematical algorithm can be employed to handle more complex d-c or a-c networks, or nonlinear networks, than the ones discussed.

It is possible to use the program to solve physical problems other than electrical network analysis: any physical problem for which an electric analogue can be made may be solved by the digital computing system. This includes potential problems of a certain kind, such as the temperature distribution problem mentioned in the paper.

Galvanometer Efficiency as a Design Parameter

F. K. HARRIS
MEMBER AIEE

IN THE ordinary use of a galvanometer, its response to a small voltage in a closed circuit is almost always the point of interest; its action can only be completely understood if the galvanometer is considered as a circuit element. The response of a galvanometer in the detector branch of a bridge or potentiometer circuit informs the operator of the direction and magnitude of the adjustment he must make to reduce the unbalance of the network. Reduced to its simplest terms, the galvanometer sees a certain resistance connected across its terminals in which a certain electromotive force (emf), the unbalanced voltage in the network, is present. The galvanometer acts in all respects like an electric motor which stalls after winding a spring (the galvanometer suspension). The useful work is represented by the energy stored in the suspensions of the deflected instrument. It is therefore proper to inquire what use the galvanometer makes of the power available at its terminals,[1] and what means can be used to make it utilize this power efficiently in its motor action.

Efficiency

If the voltage E which would appear across an open circuit in the galvanometer branch of an unbalanced network is considered as well as the circuit resistance R which is connected to the galvanometer terminals, the maximum power available to the galvanometer (considered as an energy receiver) is $E^2/(4R)$. If the time T is required for the galvanometer coil to move from its rest position to maximum deflection, the energy available to the galvanometer during the interval is $E^2T/(4R)$. The maximum deflection is logical for the observer to read whether or not he uses the technique of galvanometer reversal[2] to double effective sensitivity and to eliminate the effect of parasitic emf in the galvanometer itself. Energy storage in the suspension during the interval is $(^1/_2)\,U\theta^2$ where

U = the suspension stiffness
θ = the angular deflection

The motor efficiency can then be defined as the ratio of stored to available energy, or

$$\psi=\frac{(1/2)U\theta^2}{E^2T/(4R)}=2RU\theta^2/(E^2T) \qquad (1)$$

since the useful work of the stalling motor is done in winding its spring, i.e., is converted to potential energy in the twisted suspension.

T can be expressed as $T=T_0/(2\sqrt{1-\gamma^2})$, see Appendix, in terms of the free period T_0 of the galvanometer and the relative damping γ in the operating circuit, so that

$$\psi=4RU\theta^2\sqrt{1-\gamma^2}/(E^2T_0) \qquad (2)$$

Relative damping, defined explicitly in the Appendix, may be considered as the ratio of the existing damping to critical damping. Numerically it ranges from 0 to 1 for the underdamped galvanometer and is greater than 1 for the overdamped galvanometer. Alternatively, efficiency may be expressed in terms of the relative damping γ in the circuit, the open-circuit relative damping γ_0, and the ratio N of external critical damping resistance to galvanometer resistance. Thus it can be shown, see Appendix, that

$$\psi=\frac{4}{\pi}\sqrt{1-\gamma^2}(\gamma-\gamma_0)\left(1-\frac{\gamma-\gamma_0}{1-\gamma_0}\,\frac{1}{N+1}\right)\times\left(1+\epsilon^{-\frac{\pi\gamma}{\sqrt{1-\gamma^2}}}\right)^2 \qquad (3)$$

Efficiency is shown in Fig. 1 as a function of damping for various values of N, and for two values of open circuit damping. It is apparent from these families of

Paper 56-60, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 17, 1955; made available for printing November 18, 1955.

F. K. Harris is with the National Bureau of Standards, Washington, D. C.

The author is grateful for the wise counsel of the late Dr. Frank Wenner, who proposed this problem, and for the skill of James B. Griffin who constructed the galvanometer.

This work was supported in part by the Diamond Ordnance Fuze Laboratories and, in part, under a program of basic instrumentation in connection with the National Bureau of Standards, by the Office of Naval Research, the Office of Scientific Research of the Air Research and Development Command, and the Atomic Energy Commission.

curves that, for efficient operation, the ratio of external circuit resistance to galvanometer resistance should be high, and that the open-circuit relative damping should be as small as possible. The open-circuit damping should be kept small since energy utilized by the galvanometer for dissipative damping is converted to heat through eddy-current and windage losses during the motion of the coil, and is not available for storage as potential energy in the deflected system. It is not so obvious that, for high efficiency, the resistance of the circuit must be large compared to the resistance of the galvanometer. This apparent paradox is resolved when it is considered that the transient motional impedance of the galvanometer rather than its static resistance must be matched to the circuit for maximum energy transfer during the motion.

In practice it is usually not difficult to realize a design in which the ratio of circuit resistance to coil resistance is 10 or more at critical damping, and in which the open-circuit relative damping is no more than 0.01 or 0.02. Thus it may be expected that about 70 per cent of the energy available at the galvanometer terminals can be employed usefully during the interval in which the moving system goes from its rest position to maximum deflection. (The maximum energy utilization will be somewhat less if the resistance of the galvanometer suspensions is a significant part of the total resistance.)

Power and Energy Relations

It is interesting to observe the manner in which energy is accepted by the galvanometer during its motion, and the way in which the accepted power is apportioned among the various energy absorbing mechanisms.

The equation of motion of the moving-coil galvanometer is[3]

$$P\ddot{\theta}+[K+G^2/(R+R_g)]\dot{\theta}+U\theta=GE/(R+R_g) \tag{4}$$

where

P = the moment of inertia of the moving system
K = the coefficient of dissipative damping
G = the motor constant, i.e., the air-gap field multiplied by coil area turns

If the potential energy of the system at any instant is $(^1/_2)U\theta^2$, the potential power may be defined as the rate of energy storage in this form, the time derivative of potential energy. Similarly kinetic power may be defined as the time rate of change of kinetic energy, or

$$\frac{d}{dt}\left[(^1/_2)P\left(\frac{d\theta}{dt}\right)^2\right]$$

The damping power is $K(d\theta/dt)^2$, since $K(d\theta/dt)$ is the dissipative damping torque. The sum of these three quantities (potential + kinetic + damping power) comprises the total motor power of the system, that is ei, the product of the instantaneous back emf of the galvanometer and the current in the circuit. There is one additional component of power, i^2R_g, the joule power. The total power accepted by the galvanometer is the sum of motor power and joule power at any instant. The back emf is given by the expression $e=G(d\theta/dt)$, and the current is $i=(E-e)/(R+R_g)$.

Galvanometer current and back emf are plotted against time in Fig. 2 for a particular galvanometer in which the operating relative damping is 0.707. (This particular value of damping (0.707, or $1/\sqrt{2}$) was used to reduce the labor of computing power and energy relations, and because a relative damping of approximately this value is favorable to galvanometer operation in many instances.) The open-circuit relative damping is 0.017, and the ratio of circuit resistance to coil resistance is about 10 to 1 at critical damping. Figs. 3 and 4 show the distribution of power and energy respectively for the same galvanometer. The co-ordinates of all these graphs have been normalized, and the deflection is maximum when $\omega t=\pi$. It should be noted that, during the interval when the potential power is more than the power available from the circuit, the excess is supplied from kinetic power since the kinetic energy of the system is decreasing at this time. It may also be noted that relatively little energy is transformed into heat while the galvanometer is being deflected. A much larger amount is stored as potential energy. Under steady-state conditions, energy is used only to supply heat.

Galvanometer Design Considerations

In a specific application, the circuit resistance may be known with which the galvanometer is to be used as well as the voltage of unbalance that must be observed. With these data, the expression for efficiency furnishes a convenient starting point in the design of a suitable galvanometer.

The expression $\psi E^2T_0/(4R2\sqrt{1-\gamma^2}) = (^1/_2)U\theta^2$ shows the energy storage that may be expected in a given suspension during the time required to attain maximum deflection. This may be written

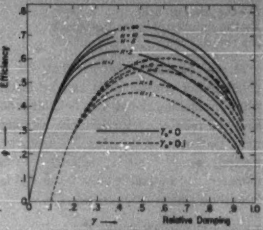

Fig. 1. Galvanometer efficiency as a function of damping

$$(\theta/E)^2=\psi T_0/(4RU\sqrt{1-\gamma^2}) \tag{5}$$

giving the expected voltage sensitivity in terms of the circuit resistance, the suspension stiffness, the free period of the galvanometer, and the relative damping at which it is to be operated. Alternatively, this expression may be used to calculate the combination of free period and suspension stiffness which will achieve a required sensitivity in a given circuit at a prescribed damping.

Since $T_0 = 2\pi\sqrt{P/U}$, sensitivity may also be expressed as a function of moment of inertia, suspension stiffness, and damping, in the relation

$$(\theta/E)^2=\pi\psi\sqrt{PU}/(2RU^2\sqrt{1-\gamma^2}) \tag{6}$$

If the physical size and the magnet structure of the instrument are specified, approximate values can be calculated for the moment of inertia P of the moving system and the stiffness U of the suspensions. Thus the maximum voltage sensitivity that can be achieved in a galvanometer design is limited by the length and cross section of the available suspension material as well as by the circuit resistance and the galvanometer period.

To complete the design the number of turns in the coil and the air-gap field must be specified. The motor constant of the galvanometer can be derived from the expression

$$R+R_g=G^2/[2\sqrt{PU}(\gamma-\gamma_0)] \tag{7}$$

Here it may be considered that the motor constant of the instrument is being fitted to the given circuit resistance for the desired value of operating relative damping. If the coil resistance can be kept low compared to circuit resistance (desirable for high efficiency), and if the open-circuit damping is small.

$$G\approx\sqrt{2\gamma R\sqrt{PU}} \tag{8}$$

which is nearly enough for present purposes. Now $G = BnA$ where

B = the air-gap field
n = the number of turns in the coil
A = the coil area

It will be seen therefore that, for a given motor constant, R_g can be made small by making the air-gap field large so that the number of turns in the winding may be small. Of course it must be realized that in a strong field the galvanometer will be stable only if the coil is free from magnetic impurities.

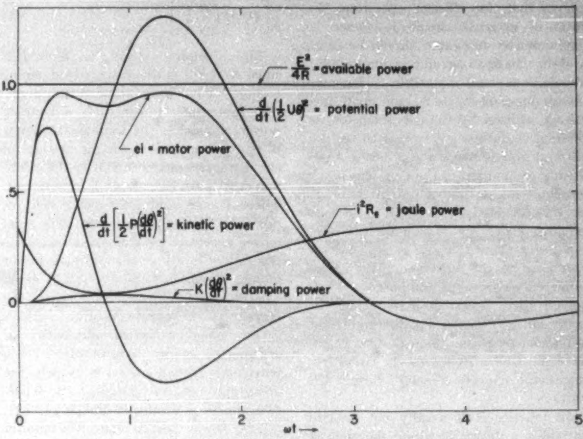

Fig. 3. Galvanometer power distribution during motion

DESIGN DETAILS

To illustrate the application of the foregoing equations, the design of a particular taut-suspension galvanometer will be considered in detail. The magnetic circuit is arranged oppositely to that generally used in galvanometer construction. The cylindrical core and shaped-pole pieces are of Alnico V. The core magnet and pole-piece structure are identical with those used in a particular Weston Sensitrol relay. The return magnetic circuit is a soft iron horseshoe to which the Alnico pole pieces are soldered. The air gap is 2 millimeters and has a field of 3,500 gausses. The coil is square, 11 millimeters on a side. No. 40 American Wire gauge copper wire was available, which had been especially prepared to be free from magnetic impurities, and was used in the construction. A collapsible winding form which accepts 15 turns of no. 40 wire per layer was used. To preserve mechanical symmetry in the moving system, two complete layers (30 turns) were wound on the form. This construction permitted the moment of inertia of the moving system to be computed accurately in advance. Only a portion of this total winding was used actively. Connections to the suspensions were made at one end of the coil and at an appropriate tap point.

The magnet structure and coil size being fixed, the design may proceed in either of two directions. If a particular voltage sensitivity at a chosen damping in a given circuit were desired, equation 6 could be used to select the suspension needed. Finally, equation 8 (or equation 7) would give the number of coil turns needed to fit the galvanometer to the given circuit. Alternatively, if it were desired to use suspensions of a particular length and cross section, their stiffness would be determined, and the coil turns required for operation at a chosen damping in the given circuit could be computed from equation 7 or 8. The expected voltage sensitivity and period could then be computed for the completed design. In either instance, the design equations describe the performance of the galvanometer with good accuracy.

In the particular design under consideration, it was desired that the galvanometer have the highest possible voltage sensitivity in a 50-ohm circuit, within the limits imposed by the available physical structure, with an assigned relative damping of 0.7. To this end, the smallest available suspension material was chosen. This was a 0.7-mil round wire of a copper-silver alloy having high strength and a conductivity over 70 per cent that of copper. (The ultimate strength of this wire, 150,000 pounds per square inch, corresponds to a loading of about 25 grams on the suspension.) Upper and lower suspensions 3 centimeters in length could be accommodated in an available mounting frame, and the stiffness of the suspensions could be computed. At this point the free period of the galvanometer could also be predicted from the relation $T_0=2\pi\sqrt{P/U}$. The predicted period, 1.38 seconds, was quite close to the actual period, 1.4 seconds, observed on the completed galvanometer, which indicated that the computed values of moment of inertia and stiffness were good.

The chosen suspensions have a combined resistance of about 6 ohms and, since a coil resistance of 3 ohms could be expected, the galvanometer resistance is

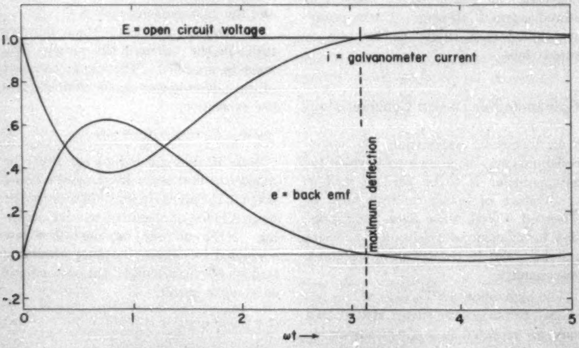

Fig. 2. Galvanometer current and back emf during motion

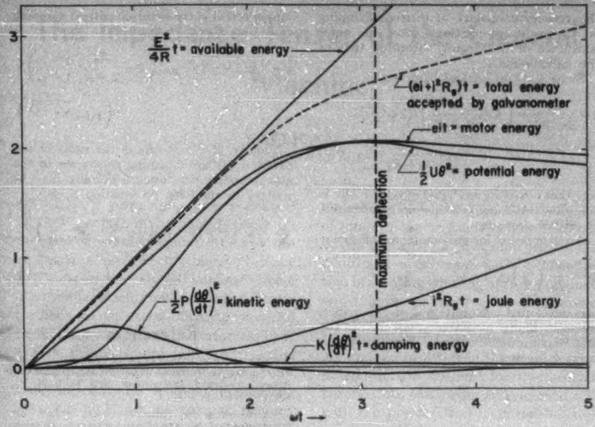

Fig. 4. Galvanometer energy distribution during motion

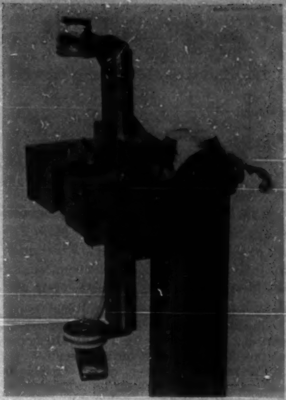

Fig. 6. Side view of galvanometer

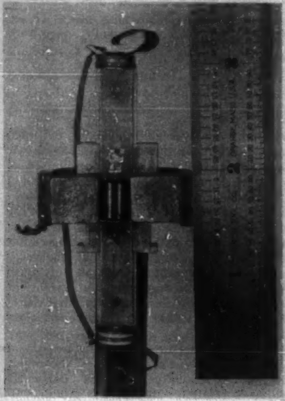

Fig. 5. Front view of galvanometer

9 ohms. Thus, in a 50-ohm circuit, the ratio of circuit to galvanometer resistance is only about 5, so that equation 7 rather than equation 8 was used to compute the motor constant of the galvanometer. A value of 0.725 times 10^5 was obtained as the desired motor constant, and this (in the available air-gap field of 3,500 gausses) set the value 17.1 as the number of turns needed to match the galvanometer to the operating circuit at the desired damping. Since the current enters and leaves the coil at opposite ends, the closest possible approximation to the desired winding is $17^1/_2$ turns. It is to be expected, therefore, that the actual damping would be slightly higher than the desired value.

The expected voltage sensitivity in the 50-ohm circuit remains to be computed. Because of the small cross section and high resistance of the suspensions, and because of the rather low operating-circuit resistance, the ratio of circuit to galvanometer resistance was much lower (5 to 1) than is desirable for best motor efficiency. Thus, under the existing conditions, an efficiency of only about 0.6 would be realized. This value was used in equation 6, and the predicted voltage sensitivity was 0.9 millimeter per microvolt (at 1 meter) in the 50-ohm circuit. Fig. 5 shows the front view and Fig. 6 the side view of a galvanometer.

Conclusion

The operating efficiency of a moving-coil galvanometer has been expressed as the ratio of stored energy to energy available at its terminals during its motion, and the power and energy utilization have been calculated in a typical example. Simple equations are given for adapting a galvanometer design to a particular set of operating conditions and for calculating the resulting voltage sensitivity. The validity of these equations has been demonstrated in a practical design of a galvanometer of high sensitivity and short period.

The use of a magnet design intermediate between the usual horseshoe type (with soft iron pole pieces and core) and the core-magnet structure[3] recently developed for indicating instruments provides a very compact structure and permits the realization of a strong air-gap field and, consequently, of efficient operation in a galvanometer having a length of 3 inches and a maximum cross section of about 1 square inch.

Appendix. Development of Equations

The equation of motion of the moving-coil galvanometer can be stated in the form[4]

$$P\ddot{\theta}+[K+G^2/(R+R_g)]\dot{\theta}+U\theta=GE/(R+R_g)$$

where

P = the moment of inertia of the moving system
K = the coefficient of dissipative damping
U = the stiffness of the suspension
G = the motor constant (air-gap field × coil-area turns)
R = the external circuit resistance
R_g = the galvanometer resistance (coil + suspension)
E = the open-circuit voltage at the galvanometer terminals

The solution of this equation, for underdamped motion, is

$$\theta=\theta_F\left[1-\frac{T_1}{T_0}\epsilon^{-\frac{At}{2P}}\sin\left(\frac{2\pi t}{T_1}+\tan^{-1}\frac{4\pi P}{AT_1}\right)\right]$$

where

$\theta_F=GE/[U(R+R_g)]$ = the steady-state deflection
$T_0=2\pi\sqrt{P/U}$ = the free period
$T_1=T_0/\sqrt{1-A^2/(4PU)}$ = the actual period in the operating circuit

$A=K+G^2/(R+R_g)=$ the coefficient of total damping (including both dissipative and conservative damping)

This solution may be written in the form

$$\theta=\theta_F\left[1-\frac{1}{\sqrt{1-\gamma^2}}\epsilon^{\frac{-2\pi\gamma t}{T_0}}\times \sin\left(\frac{2\pi t}{T_0}\sqrt{1-\gamma^2}+\sin^{-1}\sqrt{1-\gamma^2}\right)\right]$$

where

$\gamma=AT_0/(4\pi P)=A/(2\sqrt{PU})$ is the relative damping (the ratio of the actual coefficient to that required for critical damping)

The value of the first maximum deflection is $\theta_1=\theta_F\left(1+\epsilon^{\frac{-\pi\gamma}{\sqrt{1-\gamma^2}}}\right)$ and it occurs at a time $T=T_0/(2\sqrt{1-\gamma^2})$ after the voltage E is impressed on the circuit.

The relation between circuit resistance and relative damping can be expressed as $R+R_g=(R_c+R_g)(1-\gamma_0)/(\gamma-\gamma_0)$.

where

$R_c=$ the external circuit resistance (usually called *CDRX*) required for critical damping

$\gamma_0=K/(2\sqrt{PU})=$ the relative damping on open circuit

It may be noted from this relation that the conservative part of relative damping is inversely proportional to the total resistance of the circuit, including that of the galvanometer.

Since $\gamma=1$ at critical damping

$$1=\frac{A_c}{2\sqrt{PU}}=\left(K+\frac{G^2}{R_c+R_g}\right)/(2\sqrt{PU})$$
$$=\gamma_0+\frac{G^2}{R_c+R_g}/(2\sqrt{PU})$$

so that $R_c+R_g=G^2/[2(1-\gamma_0)\sqrt{PU}]$ is the total resistance (circuit+galvanometer) at critical damping.

An expression for galvanometer efficiency

$$\psi=\frac{4RU}{T_0}\left(\frac{\theta}{E}\right)^2\sqrt{1-\gamma^2}$$

was developed as equation 2 of this paper, efficiency being calculated at the time of the first maximum deflection. For this maximum deflection

$$\frac{\theta}{E}=\frac{G}{(R+R_g)U}\left(1+\epsilon^{\frac{-\pi\gamma}{\sqrt{1-\gamma^2}}}\right)$$

and

$$\psi=\frac{2RG^2\sqrt{1-\gamma^2}}{\pi(R+R_g)^2\sqrt{PU}}\left(1+\epsilon^{\frac{-\pi\gamma}{\sqrt{1-\gamma^2}}}\right)^2$$

If the galvanometer design parameters G, P, and U are eliminated, and the actual circuit resistance is replaced by its equivalent in terms of the external critical damping resistance R_c

$$\psi=\frac{4}{\pi}\sqrt{1-\gamma^2}(\gamma-\gamma_0)\left(1-\frac{R_g}{R_c+R_g}\frac{\gamma-\gamma_0}{1-\gamma_0}\right)\times \left(1+\epsilon^{\frac{-\pi\gamma}{\sqrt{1-\gamma^2}}}\right)^2$$

Finally, if $N=R_c/R_g$ is the ratio of the external critical damping resistance to the galvanometer resistance, efficiency may be written in the form of equation 3, as

$$\psi=\frac{4}{\pi}\sqrt{1-\gamma^2}(\gamma-\gamma_0)\left(1-\frac{\gamma-\gamma_0}{1-\gamma_0}\frac{1}{N+1}\right)\times \left(1+\epsilon^{\frac{-\pi\gamma}{\sqrt{1-\gamma^2}}}\right)^2$$

Discussion

H. N. Hayward (University of Illinois, Urbana, Ill.): The use of the word "efficiency" in describing the effectiveness of galvanometer response in this instance does not seem to be quite appropriate. The standard definition of "efficiency"[1] is, "The efficiency of a device with respect to a physical quantity which may be stored, transferred or transformed by the device is the ratio of the useful output of the quantity to its total input. Unless specifically stated otherwise, the term *efficiency* means efficiency with respect to power." There seems to be no question regarding the appropriate application of the first sentence of the definition. This comment refers particularly to the second sentence of the definition which, in effect, states that if other than power efficiency is referred to, that fact should be specifically stated. In this instance, energy efficiency rather than power efficiency is involved. There are already so many definitions of efficiency, each of which is unique for a given application, that it would appear highly desirable to add a qualifying or limiting adjective in this instance so that there can be no doubt about just what is meant. The primary objective in selecting a galvanometer for use in a bridge or potentiometer circuit for making null measurements is to be able to detect a sufficiently small amount of unbalance to establish that no significant unbalance actually exists. It is also because of this fact that the use of the single term "efficiency" as being appropriately descriptive is questioned. Although some thought has been given to the matter, no definite recommendation as to just what term might or should be used in place of "efficiency" has been selected. It is suggested that the matter be given further study.

The paper effectively points out that the proper basis for selecting a galvanometer is not the one that has been generally accepted and usually taken for granted. It should be of interest to have the characteristics of some of the commercially available laboratory galvanometers analyzed on the basis given in the paper, to determine the circuit characteristics under which they might be applied most effectively.

It is suggested that an effort be made to interest the galvanometer manufacturers in adding whatever information may be necessary to the galvanometer catalogue data now published to permit galvanometers to be selected in the future on the basis outlined in this excellent paper.

1. Definitions of Electrical Terms. *ASA C42-1941*, American Standards Association, New York, N. Y., 1941, paragraph 05.50.060, p. 60.

F. K. Harris: As Prof. Hayward points out, the term "efficiency" is used here in a very special sense, and a descriptive or qualifying adjective should be employed. To describe this quantity completely the modifiers would have to indicate that it is the ratio of energy stored to energy available from the external circuit during the time required by the galvanometer to reach maximum deflection. It would appear hopeless to try to find a combination of modifiers of reasonable length which would tell the complete story. Yet this "efficiency" is very useful as a parameter in the design equation since it permits the design to be fitted to a particular operating circuit condition. The term "dynamic efficiency" might be acceptable. Perhaps this term would convey the suggestion that a transient condition is being described, and that therefore an energy rather than a power relationship is involved.

With reference to the need for additional data in galvanometer catalogues, the circuit resistance associated with a particular value of relative damping is a function of the difference between the total relative damping and the open-circuit relative damping. This relation is $(R_a+R_g)/(R_c+R_g)=(1-\gamma_0)/(\gamma_a-\gamma_0)$, where R_a is the circuit resistance corresponding to the relative damping γ_a and R_c (the external critical damping resistance of the galvanometer) is the circuit resistance corresponding to critical damping. It would therefore be most helpful if galvanometer manufacturers would give values of open-circuit relative damping for their instruments or, where this constant is very small, would indicate approximately the maximum value it might be expected to have. The galvanometer resistance R_g, and the external critical damping resistance are usually available as catalogue information. There are also situations in which it would be helpful to know how R_g is divided between coil and suspension resistance.

The Impedance Tensor of the General Machine

YAO-NAN YU
NONMEMBER AIEE

TWENTY years ago, Kron published the first part of his pioneer work on the application of tensors to the analysis of rotating electric machinery.[1] Since that time, many valuable studies[2-6] have been made which firmly establish tensor methods as an extraordinarily powerful method for analyzing the performance of electric machines and other complicated physical networks. With the aid of this tool, the engineer can solve intricate network problems in routine manner, thereby obtaining solutions directly.

This paper advances a study of the impedance tensors of general electric machines which are of salient-pole construction, and have m stator windings and n rotor windings. No restrictions on phase symmetry, such as an equal number of turns or an equal spacing of phase axes, are assumed.

The first part of the paper deals with the impedance tensors of a general machine with stationary winding axes; this is essentially a general commutating machine and includes induction machines of the squirrel-cage type as a special class. The derivation of the general impedance tensor is begun for a machine with only one stator winding and one rotor winding, and is then extended to the general case of m stator windings and n rotor windings. The paper then deals with the impedance tensor of a general machine with moving winding axes; this includes both synchronous machines and induction machines of slip-ring type as special classes. Since stationary winding axes can be considered as a special case of the general moving winding axes, the result of the second part of the paper naturally includes that of the first part.

In Appendix I the "back electromotive force (emf) principle" is introduced. With the aid of the physical concept underlying this principle, the coefficient of rotation can be easily determined. In Appendix II the physical interpretation of additional speed emf due to introduction of rotating winding axes is examined, and a simple method for the calculation of additional speed impedance is derived. In Appendix III, equations 38 and 46 are derived in detail in the usual form of differential equations from cross-field theory. As this paper is concerned only with the presentation of principles, only one example of an application is given, in Appendix IV. In this a short-circuited single-phase alternator is analyzed.

Direct Impedance Tensor of General Machine with Stationary Winding Axes

The general machine is assumed to have one stator winding a and one rotor winding u, as shown in Fig. 1, both winding axes being stationary in space though winding u itself is rotating with rotor speed $p\theta$. When stationary 2-reaction axes d and q are chosen as reference axes, with d leading q by 90 degrees (which implies that the clockwise rotating conductors meet d first and q 90 degrees later) the component impedances of the machine can be expressed as in the following matrix

$$Z=\begin{array}{c|cc|cc|}
 & d_a & q_a & d_u & q_u \\
\hline
d_a & L_{da}p & 0 & M_{dudu}p & 0 \\
q_a & 0 & L_{qa}p & 0 & M_{quqa}p \\
\hline
d_u & M_{dadu}p & M_{qadu}p\theta & L_{du}p & M_{qudu}p\theta \\
q_u & -M_{daqu}p\theta & M_{qaqu}p & -M_{duqu}p\theta & L_{qu}p \\
\hline
\end{array} \qquad (1)$$

where

$$L_{da}=N_a'N_aP_d\sin^2\theta_a$$
$$L_{qa}=N_a'N_aP_q\cos^2\theta_a$$
$$M_{dadu}=N_a'N_uP_d\sin\theta_a\sin\theta_u$$
$$M_{qaqu}=N_a'N_uP_q\cos\theta_a\cos\theta_u$$
$$M_{daqu}=N_a'N_uP_d\sin\theta_a\cos\theta_u$$
$$M_{qadu}=N_a'N_uP_q\cos\theta_a\sin\theta_u$$
$$M_{duda}=N_u'N_aP_d\sin\theta_u\sin\theta_a \qquad (2)$$
$$M_{quqa}=N_u'N_aP_q\cos\theta_u\cos\theta_a$$
$$L_{du}=N_u'N_uP_d\sin^2\theta_u$$
$$L_{qu}=N_u'N_uP_q\cos^2\theta_u$$
$$M_{duqu}=N_u'N_uP_d\sin\theta_u\cos\theta_u$$
$$M_{qudu}=N_u'N_uP_q\cos\theta_u\sin\theta_u$$

where N', N = effective number of turns of the exciting and the excited windings respectively, and P_d, P_q = permeance of the respective axes. A sinusoidal distribution of permeance in the air gap is assumed. The subscripts attached to the inductance refer successively to the exciting and the excited coils. The coefficient of rotation g of equation 1 is given in equation 3, as determined in Appendix I.

$$g=\begin{array}{c|cc|cc|}
 & d_a & q_a & d_u & q_u \\
\hline
d_a & & 0 & & 0 \\
q_a & 0 & & 0 & \\
\hline
d_u & & 1 & & 1 \\
q_u & -1 & & -1 & \\
\hline
\end{array} \qquad (3)$$

To find the direct self- and mutual-impedance tensors of a and u, a few transformations are necessary. The transformation matrix is of the following form

$$C=\begin{array}{c|c|c|}
 & i_a & i_u \\
\hline
i_{da} & 1 & 0 \\
i_{qa} & 1 & 0 \\
i_{du} & 0 & 1 \\
i_{qu} & 0 & 1 \\
\hline
\end{array} \qquad (4)$$

$$C_tZC=\begin{array}{c|c|c|}
 & a & u \\
\hline
a & (L_{da}+L_{qa})p & (M_{duda}+M_{quqa})p \\
u & (M_{dadu}+M_{qaqu})p-(M_{daqu}-M_{qadu})p\theta & (L_{du}+L_{qu})p-(M_{duqu}-M_{qudu})p\theta \\
\hline
\end{array} \qquad (5)$$

The result is equation 5, which shows that the impedance of a whole coil is the total sum of the self- and mutual-impedances of its d-, q- components. Therefore the same result can be obtained by summing equation 1 the various items in each block separated by heavy lines.

Next, the general machine with two rotor windings u and v, as shown in Fig. 2, is considered. With d and q chosen as reference axes as before, the component impedances of the machine can be expressed as

$$Z=\begin{array}{c|cc|cc|}
 & d_u & q_u & d_v & q_v \\
\hline
d_u & L_{du}p & M_{qudu}p\theta & M_{dvdu}p & M_{qvdu}p\theta \\
q_u & -M_{duqu}p\theta & L_{qu}p & -M_{dvqu}p\theta & M_{qvqu}p \\
\hline
d_v & M_{dudv}p & M_{qudv}p\theta & L_{dv}p & M_{qvdv}p\theta \\
q_v & -M_{duqv}p\theta & M_{quqv}p & -M_{dvqv}p\theta & L_{qv}p \\
\hline
\end{array} \qquad (6)$$

Paper 56-122, recommended by the AIEE Basic Sciences Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1956. Manuscript submitted February 14, 1955; made available for printing December 22, 1955.

YAO-NAN YU is with the National Taiwan University, Taipei, Taiwan, China.

The author wishes to express appreciation for the assistance given by his colleagues, Prof. C. L. Sheng, Hsu Chang, and Hwei-Piao Hsu, in the preparation of this paper.

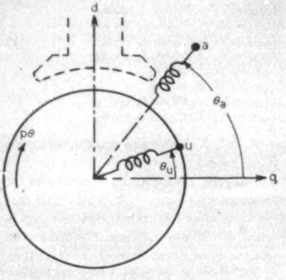

Fig. 1. One stator winding and one rotor winding of general electric machine

where

$$\begin{aligned}
L_{du}&=N_u'N_uP_d\sin^2\theta_u\\
L_{qu}&=N_u'N_uP_q\cos^2\theta_u\\
M_{duqu}&=N_u'N_uP_d\sin\theta_u\cos\theta_u\\
M_{qudu}&=N_u'N_uP_q\cos\theta_u\sin\theta_u\\
M_{dvdu}&=N_v'N_uP_d\sin\theta_v\sin\theta_u\\
M_{qvqu}&=N_v'N_uP_q\cos\theta_v\cos\theta_u\\
M_{dvqu}&=N_v'N_uP_d\sin\theta_v\cos\theta_u\\
M_{qvdu}&=N_v'N_uP_q\cos\theta_v\sin\theta_u\\
M_{dudv}&=N_u'N_vP_d\sin\theta_u\sin\theta_v\\
M_{quqv}&=N_u'N_vP_q\cos\theta_u\cos\theta_v\\
M_{duqv}&=N_u'N_vP_d\sin\theta_u\cos\theta_v\\
M_{qudv}&=N_u'N_vP_q\cos\theta_u\sin\theta_v\\
L_{dv}&=N_v'N_vP_d\sin^2\theta_v\\
L_{qv}&=N_v'N_vP_q\cos^2\theta_v\\
M_{dvqv}&=N_v'N_vP_d\sin\theta_v\cos\theta_v\\
M_{qvdv}&=N_v'N_vP_q\cos\theta_v\sin\theta_v
\end{aligned}\tag{7}$$

the coefficient of rotation being equation 8.

$$g=\begin{array}{c|c|c|c|c|}
 & d_u & q_u & d_v & q_v\\ \hline
d_u & & 1 & & 1\\ \hline
q_u & -1 & & -1 & \\ \hline
d_v & & 1 & & 1\\ \hline
q_v & -1 & & -1 & \\ \hline
\end{array}\tag{8}$$

After transformation, the direct self- and mutual impedances are as shown in equation 9

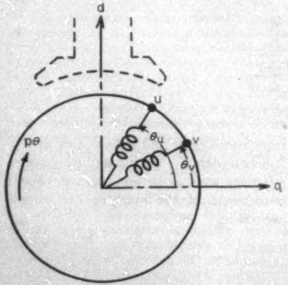

Fig. 2. Two rotor windings of general electric machine

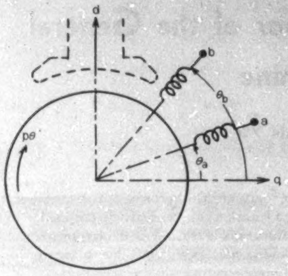

Fig. 3. Two stator windings of general electric machine

$$C_tZC=\begin{array}{c|c|c|}
 & u & v\\ \hline
u & (L_{du}+L_{qu})p-(M_{duqu}-M_{qudu})p\theta & (M_{dvdu}+M_{qvqu})p-(M_{dvqu}-M_{qvdu})p\theta\\ \hline
v & (M_{dudv}+M_{quqv})p-(M_{duqv}-M_{qudv})p\theta & (L_{dv}+L_{qv})p-(M_{dvqv}-M_{qvdv})p\theta\\ \hline
\end{array}\tag{9}$$

the transformation matrix being

$$C=\begin{array}{c|c|c|}
 & i_u & i_v\\ \hline
i_{du} & 1 & 0\\ \hline
i_{qu} & 1 & 0\\ \hline
i_{dv} & 0 & 1\\ \hline
i_{qv} & 0 & 1\\ \hline
\end{array}\tag{10}$$

Next, the general machine with two stator windings a and b, as shown in Fig. 3, is considered. The component impedances of this machine are the following

$$Z=\begin{array}{c|c|c|c|c|}
 & d_a & q_a & d_b & q_b\\ \hline
d_a & L_{da}p & 0 & M_{dbda}p & 0\\ \hline
q_a & 0 & L_{qa}p & 0 & M_{qbqa}p\\ \hline
d_b & M_{dadb}p & 0 & L_{db}p & 0\\ \hline
q_b & 0 & M_{qaqb}p & 0 & L_{qb}p\\ \hline
\end{array}\tag{11}$$

where

$$\begin{aligned}
L_{da}&=N_a'N_aP_d\sin^2\theta_a\\
L_{qa}&=N_a'N_aP_q\cos^2\theta_a\\
M_{dadb}&=N_a'N_bP_d\sin\theta_a\sin\theta_b\\
M_{qaqb}&=N_a'N_bP_q\cos\theta_a\cos\theta_b\\
M_{dbda}&=N_b'N_aP_d\sin\theta_b\sin\theta_a\\
M_{qbqa}&=N_b'N_aP_q\cos\theta_b\cos\theta_a\\
L_{db}&=N_b'N_bP_d\sin^2\theta_b\\
L_{qb}&=N_b'N_bP_q\cos^2\theta_b
\end{aligned}\tag{12}$$

The direct impedance tensor is given by

$$C_tZC=\begin{array}{c|c|c|}
 & a & b\\ \hline
a & (L_{da}+L_{qa})p & (M_{dbda}+M_{qbqa})p\\ \hline
b & (M_{dadb}+M_{qaqb})p & (L_{db}+L_{qb})p\\ \hline
\end{array}\tag{13}$$

the transformation matrix being

$$C=\begin{array}{c|c|c|}
 & i_a & i_b\\ \hline
i_{da} & 1 & 0\\ \hline
i_{db} & 1 & 0\\ \hline
i_{qa} & 0 & 1\\ \hline
i_{qb} & 0 & 1\\ \hline
\end{array}\tag{14}$$

Finally, the general machine in its broadest sense is considered. It has m stator windings and n rotor windings, all winding axes being stationary in space and arbitrarily spaced, as shown in Fig. 4. By referring to equations 5, 9, and 13, the direct-impedance tensor of this machine can be immediately written as the following:

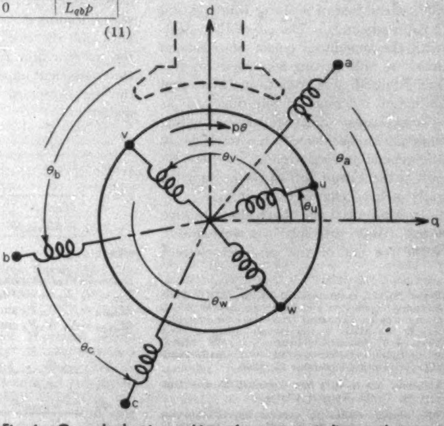

Fig. 4. General electric machine of m stator windings and n rotor windings, with 2-reaction axes d and q shown

$$C_tZC=\begin{array}{c|c|c|c|c|c|c|c|c|}
 & a & b & .. & c & u & v & .. & w \\ \hline
a & \begin{matrix} r_a+l_ap \\ +(L_{da}+L_{qa})p \end{matrix} & (M_{dbda}+M_{qbqa})p & .. & .. & (M_{duda}+M_{quqa})p & (M_{dvda}+M_{qvqa})p & .. & .. \\ \hline
b & (M_{dadb}+M_{qacb})p & \begin{matrix} r_b+l_bp \\ +(L_{db}+L_{qb})p \end{matrix} & .. & .. & (M_{dudb}+M_{quqb})p & (M_{dvdb}+M_{qvqb})p & .. & .. \\ \hline
.. & \dots & \dots & .. & .. & \dots & \dots & .. & .. \\ \hline
c & \dots & \dots & .. & .. & \dots & \dots & .. & .. \\ \hline
u & \begin{matrix} (M_{dadu}+M_{qaqu})p \\ -(M_{daqu}-M_{qadu})p\theta \end{matrix} & \begin{matrix} (M_{dbdu}+M_{qbqu})p \\ -(M_{dbqv}-M_{qbdu})p\theta \end{matrix} & .. & .. & \begin{matrix} r_u+l_up \\ +(L_{du}+L_{qu})p \\ -(M_{duqu}-M_{qudu})p\theta \end{matrix} & \begin{matrix} (M_{dvdu}+M_{qvqu})p \\ -(M_{dvqu}-M_{qvdu})p\theta \end{matrix} & .. & .. \\ \hline
v & \begin{matrix} (M_{dadv}+M_{qaqv})p \\ -(M_{daqv}-M_{qadv})p\theta \end{matrix} & \begin{matrix} (M_{dbdv}+M_{qbqv})p \\ -(M_{dbqv}-M_{qbdv})p\theta \end{matrix} & .. & .. & \begin{matrix} (M_{dudv}+M_{quqv})p \\ -(M_{duqv}-M_{qudv})p\theta \end{matrix} & \begin{matrix} r_v+l_vp \\ +(L_{dv}+L_{qv})p \\ -(M_{dvqv}-M_{qvdv})p\theta \end{matrix} & .. & .. \\ \hline
.. & \dots & \dots & .. & .. & \dots & \dots & .. & .. \\ \hline
w & \dots & \dots & .. & .. & \dots & \dots & .. & .. \\ \hline
\end{array} \qquad (15)$$

In equation 15, self-leakage impedances have been included. The various component inductances are

$$L_{da}+L_{qa}=N_a'N_a(P_d\sin^2\theta_a+P_q\cos^2\theta_a)$$
$$L_{db}+L_{qb}=N_b'N_b(P_d\sin^2\theta_b+P_q\cos^2\theta_b)$$
$$M_{dadb}+M_{qbqa}=N_b'N_a(P_d\sin\theta_a\sin\theta_b+P_q\cos\theta_a\cos\theta_b)$$
$$M_{dbda}+M_{qbqa}=N_b'N_a(P_d\sin\theta_b\sin\theta_a+P_q\cos\theta_b\cos\theta_a)$$
$$M_{dadu}+M_{qaqu}=N_a'N_u(P_d\sin\theta_a\sin\theta_u+P_q\cos\theta_a\cos\theta_u)$$
$$M_{daqu}-M_{qadu}=N_a'N_u(P_d\sin\theta_a\cos\theta_u-P_q\cos\theta_a\sin\theta_u)$$
$$M_{dbdv}+M_{qbqv}=N_b'N_v(P_d\sin\theta_b\sin\theta_v+P_q\cos\theta_b\cos\theta_v)$$
$$M_{dbqv}-M_{qbdv}=N_b'N_v(P_d\sin\theta_b\cos\theta_v-P_q\cos\theta_b\sin\theta_v)$$
$$M_{dadv}+M_{qaqv}=N_a'N_v(P_d\sin\theta_a\sin\theta_v+P_q\cos\theta_a\cos\theta_v)$$
$$M_{daqv}-M_{qadv}=N_a'N_v(P_d\sin\theta_a\cos\theta_v-P_q\cos\theta_a\sin\theta_v)$$
$$M_{dbdu}+M_{qbqu}=N_b'N_u(P_d\sin\theta_b\sin\theta_u+P_q\cos\theta_b\cos\theta_u)$$
$$M_{dbqu}-M_{qbdu}=N_b'N_u(P_d\sin\theta_b\cos\theta_u-P_q\cos\theta_b\sin\theta_u)$$
$$M_{duda}+M_{quqa}=N_u'N_a(P_d\sin\theta_u\sin\theta_a+P_q\cos\theta_u\cos\theta_a)$$
$$M_{dvdb}+M_{qvqb}=N_v'N_b(P_d\sin\theta_v\sin\theta_b+P_q\cos\theta_v\cos\theta_b)$$
$$M_{dudb}+M_{quqb}=N_u'N_b(P_d\sin\theta_u\sin\theta_b+P_q\cos\theta_u\cos\theta_b)$$
$$M_{dvda}+M_{qvqa}=N_v'N_a(P_d\sin\theta_v\sin\theta_a+P_q\cos\theta_v\cos\theta_a)$$
$$L_{du}+L_{qu}=N_u'N_u(P_d\sin^2\theta_u+P_q\cos^2\theta_u)$$
$$M_{duqu}-M_{qudu}=N_u'N_u(P_d\sin\theta_u\cos\theta_u-P_q\cos\theta_u\sin\theta_u)$$
$$L_{dv}+L_{qv}=N_v'N_v(P_d\sin^2\theta_v+P_q\cos^2\theta_v)$$
$$M_{dvqv}-M_{qvdv}=N_v'N_v(P_d\sin\theta_v\cos\theta_v-P_q\cos\theta_v\sin\theta_v)$$
$$M_{dudv}+M_{quqv}=N_u'N_v(P_d\sin\theta_u\sin\theta_v+P_q\cos\theta_u\cos\theta_v)$$
$$M_{duqv}-M_{qudv}=N_u'N_v(P_d\sin\theta_u\cos\theta_v-P_q\cos\theta_u\sin\theta_v)$$
$$M_{dvdu}+M_{qvqu}=N_v'N_u(P_d\sin\theta_v\sin\theta_u+P_q\cos\theta_v\cos\theta_u)$$
$$M_{dvqu}-M_{qvdu}=N_v'N_u(P_d\sin\theta_v\cos\theta_u-P_q\cos\theta_v\sin\theta_u)$$
$$\dots \qquad (16)$$

All the θ-angles in the foregoing equations are constant. P_d and P_q are equal for the nonsalient pole machine.

In Kron's analysis of electric machines, two primitive types are assumed as starting point. The first one consists of four windings (ds, qs, dr, qr), two (ds, qs) on the stator, and the other two (dr, qr) on the rotor, each pair having one winding along a common axis d and the other along another common axis q, axes d and q being at 90 degrees in space and all winding axes and reference axes being stationary in space. This corresponds to a special case of the general commutating machine already discussed. In equation 15, let

$$\theta_a=90°,\ \theta_b=0,\ \theta_u=90°,\ \theta_v=0 \qquad (17)$$

and assume that the machine has four windings a, b, u, v only. Then the impedance tensor of this machine can be written as equation 18.

The windings a, b, u, v, equation 18, correspond, respectively, to the windings ds, qs, dr, qr of Kron's first primitive machine. Rearranging the order, we change equation 18 to equation 18(A), which checks with Kron's result,[7] given for comparison in equation 19.

$$C_tZC=\begin{array}{c|c|c|c|c|}
 & a & b & u & v \\ \hline
a & \begin{matrix} r_a+l_ap \\ +N_a'N_aP_dp \end{matrix} & 0 & N_u'N_aP_dp & 0 \\ \hline
b & 0 & \begin{matrix} r_b+l_bp \\ +N_b'N_bP_qp \end{matrix} & 0 & N_v'N_bP_qp \\ \hline
u & N_a'N_uP_dp & N_b'N_uP_qp\theta & \begin{matrix} r_u+l_up \\ +N_u'N_uP_dp \end{matrix} & N_v'N_uP_qp\theta \\ \hline
v & -N_a'N_vP_dp\theta & N_b'N_vP_qp & -N_u'N_vP_dp\theta & \begin{matrix} r_v+l_vp \\ +N_v'N_vP_qp \end{matrix} \\ \hline
\end{array} \qquad (18)$$

$$C_tZC=\begin{array}{c|c|c|c|c|}
 & a & u & v & b \\ \hline

qs & 0 & 0 & M_qp & r_{qs}+L_{sq}p \\ \hline
\end{array} \qquad (19)$$

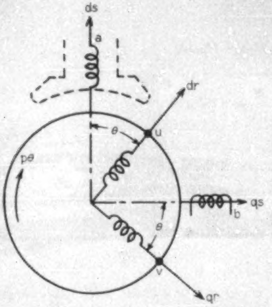

Fig. 5. Kron's second primitive machine

Direct-Impedance Tensor of General Machine with Moving Winding Axes

When moving winding axes are contemplated, additional speed emf are introduced which may be calculated by Christoffel matrix, as has been done by Kron.[8] However, as pointed out in Appendix II, these additional speed emf stem from the fact that the inductive coefficients which can be placed before p in equation 15 if constant, are no longer constants, and hence additional terms appear due to the necessity of differentiating the products involving the inductances. These additional speed reactances can be calculated by partially differentiating the exciting part of the inductive inductances and then replacing p with $p\theta$.

The terms of the impedance tensor of the general machine with moving winding axes can be derived from equation 15 with additional speed reactances added. A few typical cases are examined. Let the winding axes $u, v, \ldots, w$ of the general machine be assumed as rotating with the same speed of the rotor, while winding axes $a, b, \ldots, c$ remain stationary in space. First, $(M_{dadu}+M_{qaqu})p$ of equation 15 is considered. Since winding axis a is stationary in space and the exciting effect is not varying, there is no additional speed reactance in this case, hence

$$\frac{\partial}{\partial\theta_a}(M_{dadu}+M_{qaqu})p\theta_a=0 \tag{20A}$$

Next, $(L_{du}+L_{qu})p$ of equation 15 is considered. Since the winding axis u is moving in space and the exciting effect is varying, additional speed reactances appear in this case, and can be calculated as

$$\frac{\partial}{\partial\theta_u}(L_{du}+L_{qu})p\theta_u=N_u'N_u(P_d\cos\theta_u\sin\theta_u-P_q\sin\theta_u\cos\theta_u)p\theta_u \tag{20B}$$

Again, $(M_{dudv}+M_{quqv})$ of equation 15 is to be considered. Since the exciting effect is varying, additional speed reactances appear, which can be calculated as

$$\frac{\partial}{\partial\theta_u}(M_{dudv}+M_{quqv})p\theta_u=N_u'N_v(P_d\times\cos\theta_u\sin\theta_v-P_q\sin\theta_u\cos\theta_v)p\theta_u \tag{20C}$$

To obtain the terms of the impedance tensor of the general machine with moving axes, the additional speed reactances should be added to the corresponding terms of equation 15. For the cases studied

$$(M_{dadu}+M_{qaqu})p-(M_{daqu}-M_{qadu})p\theta_u=p\times N_a'N_u(P_d\sin\theta_a\sin\theta_u+P_q\cos\theta_a\cos\theta_u) \tag{21A}$$

$$(L_{du}+L_{qu})p-(M_{duqu}-M_{qudu})p\theta+\frac{\partial}{\partial\theta_u}(L_{du}+L_{qu})p\theta_u=p\times N_u'N_u\times(P_d\sin^2\theta_u+P_q\cos^2\theta_u) \tag{21B}$$

$$(M_{dudv}+M_{quqv})p-(M_{duqv}-M_{qudv})p\theta+\frac{\partial}{\partial\theta_u}(M_{dudv}+M_{quqv})p\theta_u=p\times N_u'N_v\times(P_d\sin\theta_u\sin\theta_v+P_q\cos\theta_u\cos\theta_v) \tag{21C}$$

where $p\theta=-p\theta_u$ in equations 21(A) and 21(B), and $p\theta=-p\theta_v$ in equation 21(C). Additively, $(L_{da}+L_{qa})p$ too can be written as $p(L_{da}+L_{qa})$, where $p\theta_a=0$.

In conclusion, the general expression for any term of the impedance tensor of the general machine with moving axes is $N_m'N_np(P_d\sin\theta_m\sin\theta_n+P_q\cos\theta_m\cos\theta_n)$.

Attention is called to the fact that the operator p operates not only on the inductance but also on the exciting current i_m. The angles θ may be constant or variable and may be different or equal. By referring to this general expression, the whole impedance tensor of the general machine with moving and/or stationary winding axes can be written immediately as follows:

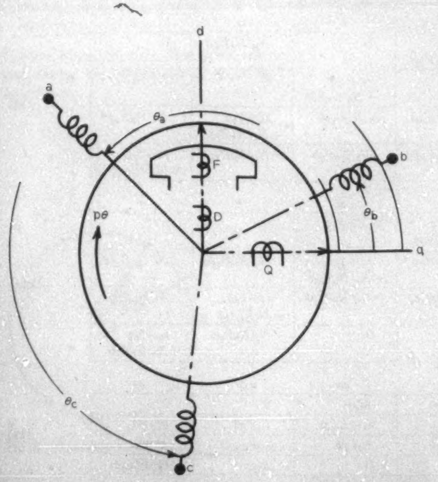

Fig. 6 (left). Three-phase 6-winding synchronous machine

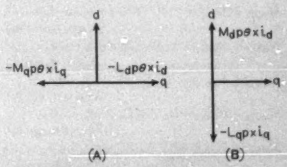

Fig. 7. Phase-angle relationship of the inductive and speed emf

A—For d-winding
B—For q-winding

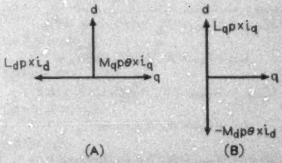

Fig. 8. Phase-angle relationship of applied inductive and speed voltages

$$

In equation 22 self-leakage impedances have been included.

A few applications are given below as illustrative of use of the equations. First, the impedance tensor of Kron's second primitive machine may be derived directly from equation 22. This machine differs from Kron's first one in that all the rotor-winding axes are now rotating with the same speed as the rotor, while the stator-winding axes remain stationary in space.

Fig. 5 shows the second primitive machine, where no windings other than a, b, u, v are included, and

$$\theta_a=90^\circ,\ \theta_b=0,\ \theta_u=90^\circ-\theta,\ \theta_v=-\theta \qquad (23)$$

Substituting equation 23 into equation 22, the order rearranged, equation 22 becomes

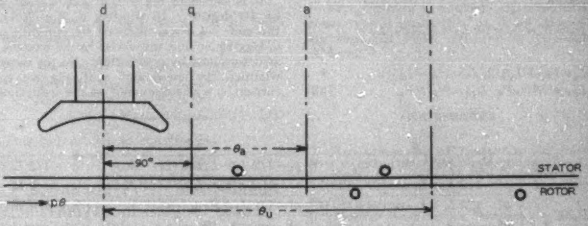

Fig. 9. Relative position between stator winding a and rotor winding u, with d-axis chosen as reference

$$
C_tZC=\begin{array}{c|c|c|c|c|}
 & a & u & v & b \\
\hline
a & r_a+1_ap+N_a'N_aP_dp & N_u'N_aP_d(\cos\theta p-\sin\theta p\theta) & -N_v'N_aP_d(\sin\theta p+\cos\theta p\theta) & 0 \\
\hline
u & N_a'N_uP_d\times(\cos\theta p-\sin\theta p\theta & r_a+1_up+N_u'N_u(P_d\cos^2\theta+P_q\sin^2\theta)p-N_u'N_u(P_d-P_q)\sin 2\theta p\theta & -N_v'N_u(P_d-P_q)\times[\sin\theta\cos\theta p+(\cos^2\theta-\sin^2\theta)p\theta] & N_b'N_uP_q\times(\sin\theta p+\cos\theta p\theta) \\
\hline
v & -N_a'N_vP_d\times(\sin\theta p+\cos\theta p\theta) & -N_u'N_v(P_d-P_q)\times[\sin\theta\cos\theta p+(\cos^2\theta-\sin^2\theta)p\theta] & r_v+1_vp+N_v'N_v(P_d\sin^2\theta+P_q\cos^2\theta)p+N_v'N_r(P_d-P_q)\sin 2\theta p\theta & N_b'N_vP_q\times(\cos\theta p-\sin\theta p\theta) \\
\hline
b & 0 & N_u'N_bP_q(\sin\theta p+\cos\theta p\theta) & N_v'N_bP_q(\cos\theta p-\sin\theta p\theta) & r_b+1_bp+N_b'N_bP_qp \\
\hline
\end{array} \qquad (24)
$$

which is identical with Kron's result[9] when a, u, v, b are replaced with ds, a, b, qs respectively, and the number of turns of windings u and v are assumed equal. For comparison, Kron's result is

$$
C_tZC=\begin{array}{c|c|c|c|c|}
 & ds & a & b & qs \\
\hline
ds & r_{ds}+L_{ds}p & M_d(\cos\theta p-\sin\theta p\theta) & -M_d(\sin\theta p+\cos\theta p\theta) & 0 \\
\hline
a & M_d(\cos\theta p-\sin\theta p\theta) & r_r(L_{dr}\cos^2\theta+L_{qr}\sin^2\theta)p+2(L_{qr}-L_{dr})\sin\theta\cos\theta p\theta & (L_{qr}-L_{dr})[\sin\theta\cos\theta p+(\cos^2\theta-\sin^2\theta)p\theta] & M_q(\sin\theta p+\cos\theta p\theta) \\
\hline
b & -M_d(\sin\theta p+\cos\theta p\theta) & (L_{qr}-L_{dr})[\sin\theta\cos\theta p+(\cos^2\theta-\sin^2\theta)p\theta] & r_r+(L_{dr}\sin^2\theta+L_{qr}\cos^2\theta)p+2(L_{dr}-L_{qr})\sin\theta\cos\theta p\theta & M_q(\cos\theta p-\sin\theta p\theta) \\
\hline
qs & 0 & M_q(\sin\theta p+\cos\theta p\theta) & M_q(\cos\theta p-\sin\theta p\theta) & r_{qs}+L_{qs}p \\
\hline
\end{array} \qquad (25)
$$

Next, the impedance tensor of 3-phase synchronous machine is derived. Fig. 6 shows such a synchronous machine, with

$$\theta_a=\theta+90^\circ,\ \theta_b=\theta_a-120^\circ,\ \theta_c=\theta_a+120^\circ,\ \theta_F=90^\circ,\ \theta_D=90^\circ,\ \theta_Q=0 \qquad (26)$$

Six windings are to be considered; namely, the symmetric 3-phase armature windings a, b, c on the stator, and the asymmetric field winding F, and amortisseur windings D and Q, on the rotor. F and D are along d-axis, while Q is along q-axis. It is assumed that the rotor was stationary while the stator was rotating with respect to the rotor.

Substituting equation 26 into equation 22, the latter becomes equation 27, in which

$$N_a=N_b=N_c=N,\ L_d=N'NP_d,\ L_q=N'NP_q \qquad (27)$$

$$L_0=(L_d+L_q)/2,\ L_2=(L_d-L_q)/2$$
$$L_{dF}=N'N_FP_d,\ L_{Qq}=N_Q'NP_q,\ \ldots \qquad (28)$$

$$C_tZC=\begin{array}{c|c|c|c|}
 & a & b & c \\ \hline
a & r_a+p1+p(L_0+L_2\cos 2\theta) & p[-1/2\,L_0+L_2\cos(2\theta-120)] & p[-1/2\,L_0+L_2\cos(2\theta+120)] \\ \hline
b & p[-1/2\,L_0+L_2\cos(2\theta-120)] & r_a+p1+p[L_0+L_2\cos(2\theta-240)] & p[-1/2\,L_0+L_2\cos 2\theta] \\ \hline
c & p[-1/2\,L_0+L_2\cos(2\theta+120)] & p[-1/2\,L_0+L_2\cos 2\theta] & r_a+p1+p[L_0+L_2\cos(2\theta+240)] \\ \hline
F & pL_{dF}\cos\theta & pL_{dF}\cos(\theta-120) & pL_{dF}\cos(\theta+120) \\ \hline
D & pL_{dD}\cos\theta & pL_{dD}\cos(\theta-120) & pL_{dD}\cos(\theta+120) \\ \hline
Q & -pL_{qQ}\sin\theta & -pL_{qQ}\sin(\theta-120) & -pL_{qQ}\sin(\theta+120) \\ \hline
\end{array}\ +$$

$$\begin{array}{c|c|c|c|}
 & F & D & Q \\ \hline
a & pL_{Fd}\cos\theta & pL_{Dd}\cos\theta & -pL_{Qq}\sin\theta \\ \hline
b & pL_{Fd}\cos(\theta-120) & pL_{Dd}\cos(\theta-120) & -pL_{Qq}\sin(\theta-120) \\ \hline
c & pL_{Fd}\cos(\theta+120) & pL_{Dd}\cos(\theta+120) & -pL_{Qq}\sin(\theta+120) \\ \hline
F & r_F+L_Fp & L_{DF}p & 0 \\ \hline
D & L_{FD}p & r_D+L_Dp & 0 \\ \hline
Q & 0 & 0 & r_Q+L_Qp \\ \hline
\end{array} \qquad (27)$$

Again, the impedance tensor of a single-phase synchronous machine can be derived. But this is only a special case of the 3-phase machine. If only one winding a on the stator and one winding u on the rotor are considered

$$\theta_a=\theta+90^\circ,\ \theta_u=\theta_F=90^\circ \qquad (29)$$

After substitution, equation 22 or equation 27 becomes

$$C_tZC=\begin{array}{c|c|c|}
 & a & u \\ \hline
a & r_a+p(L_0'+L_2\cos 2\theta) & pM\cos\theta \\ \hline
u & pM\cos\theta & r_u+pL_u \\ \hline
\end{array} \qquad (30)$$

where

$$L_0'=1+L_0,\ L_u=N_u'N_uP_d,\ M=N'N_uP_d \qquad (31)$$

With a similar procedure to that just demonstrated, the direct impedance tensor of any conceivable type of electric machine can be derived readily from equation 22 without laborious transformation.

Appendix I. Back-Emf Principle and Coefficient of Rotation

The back-emf principle[10] is advanced as follows: "When a machine is treated by cross-field theory, the speed emf of any rotating winding constitutes the back emf of the applied voltage of that winding, whether applied inductively, conductively, or simultaneously." This principle finds frequent applications. For the present discussion it serves to clarify confusions in the determination of coefficient or rotation, by interrelating the phase relations of speed and inductive emf.

It is shown in Fig. 7 that axis d leads q by 90 degrees. In winding d, Fig. 7(A), the emf $-L_dp\times i_d$, induced by current i_d, is lagging behind the d-axis by 90 degrees, as determined by convention. In the same winding, the speed emf $-M_qp\theta i_q$ due to current i_q is the back emf of the inductive emf $-L_dpi_d$, according to the back-emf principle. Therefore, the two emf are opposite in direction. By the same reasoning, in winding q, Fig. 7(B), the speed emf $M_dp\theta i_d$ and the inductive emf $-L_qpi_q$ are opposite in direction. Hence, the coefficient of rotation of the speed emf can be expressed as in equation 32.

It is an established convention and a fact of a-c circuit theory, that in a winding the applied inductive reactance voltage is opposite in phase to the induced inductive emf. By analogy, the speed reactance voltage applied is also opposite in phase to the speed emf induced. Hence, for the inductive and speed reactance voltages shown in Fig. 8, the coefficient of rotation, equation 33, is the negative of equation 32.

$$\begin{array}{c|c|c|}
 & d & q \\ \hline
d & & -1 \\ \hline
q & 1 & \\ \hline
\end{array} \qquad (32)$$

$$\begin{array}{c|c|c|}
 & d & q \\ \hline
d & & 1 \\ \hline
q & -1 & \\ \hline
\end{array} \qquad (33)$$

Appendix II. Additional Speed Emf due to Introduction of Rotating References Axes

The general equation of induced emf can be expressed as equation 34

$$e=-\frac{d\psi}{dt}=-\left(\frac{\partial\psi}{\partial t}+\frac{\partial\psi}{\partial\theta}\frac{d\theta}{dt}\right) \qquad (34)$$

where ψ is the total flux linkage of the coil, $-\partial\psi/\partial t$, the inductive emf, and $-\partial\psi/\partial\theta\, d\theta/dt$, the ordinary speed emf.

In the case of a coil with constant inductance, the inductive emf can be expressed as

$$-\partial\psi/\partial t=-\partial/\partial t(Li)=-L\,\partial i/\partial t \qquad (35)$$

But if the coil inductance is varying with space variation of excitation such as in the case of Kron's second primitive machine wherein the exciting coil on the stator excites the rotor windings in different degrees when the rotor axes assume different positions in space, or in the case of a salient-pole synchronous machine wherein the mutual inductance between the armature windings varies, due to variation of permeance in space, the inductive emf should be expressed as follows

$$-\frac{\partial\psi}{\partial t}=-\frac{\partial}{\partial t}(Li)=-\left(L\frac{\partial i}{\partial t}+\frac{\partial L}{\partial\theta_1}\frac{d\theta_1}{dt}i\right) \qquad (36)$$

The additional speed emf in this case corresponds to Christoffel's speed emf. The general speed of the rotating reference axis is represented by θ_1. In the case of holonomic system, $\theta=\theta_1$, the last item of equation 36 can be expressed as

$$e=-\left(\frac{\partial L}{\partial\theta}\right)p\theta i \qquad (37)$$

Therefore, the additional speed reactance can be calculated simply by differentiating partially those parts of the inductive reactance which vary with the space variation of excitation, and then replacing p by $p\theta$.

Variation of coil inductance in space due to the motion of the excited coil could also be introduced. But its effect on the induced emf has already been taken into account in the ordinary speed emf.

Appendix III. Derivation of Equation 1 from Cross-Field Theory

It should be pointed out that the starting point of this paper is the cross-field theory of asynchronous machines and the 2-reaction theory of synchronous machines like that of Kron. Fig. 1 is developed into Fig. 9, which shows a primitive machine of salient-pole construction having one stator winding *a* and one rotor winding *u*. Winding axis *a* displaces a constant angle θ_a from the stationary reference axis *d*, and winding axis *u* displaces a constant angle θ_u from *d*. Since cross-field theory is conceived, it is a necessity from the very beginning to treat the self- and mutual inductions of *a*, *u* windings in terms of their *d*, *q* components.

In the expression of inductances, effective turns are used, which have different meanings for exciting windings and for excited windings. For the excited winding of usual type, the chording factor f_c and winding distribution factor f_w besides the number of turns in series per winding should be taken into account. For the exciting winding, other factors should be included in the effective turns, such as $4/\pi$ to pick out the space fundamental; $1/k_s$, the reciprocal of saturation factor, to segregate the air gap ampere-turns; $2/\pi$ to average the sinusoidally variated permeance; and even Carter's coefficient k_c should be included in the effective turns, though the latter two factors $2/\pi$ and k_c may also be included in the permeance as an alternative.

When cross-field theory is utilized, both transformer emf and speed emf are induced. Now, let the *d*, *q* components of winding *a* be *da*, *qa* and those of winding *u* be *du*, *qu*. Transformer emf are induced in *du* by *da*, in *da* by *du*, in *qu* by *qa* and in *qa* by *qu*. Speed emf are induced in *du* by *qa* and in *qu* by *da*. Since *qu* is leading *du* by 90 degrees in space in the direction of rotation of the rotor, the speed emf in *qu* is leading the transformer emf in *du* by 90 degrees in time when both are excited by *da*. These emf can be written as

$$E_{dadu} = -j\sqrt{2}\pi f N_{du}\phi_{da} \tag{38}$$

$$E_{daqu} = \sqrt{2}\pi f N_{qu}\phi_{da} \tag{39}$$

This very fundamental relation offers another method in addition to that described in Appendix I for the determination of the positive and negative signs before the speed inductances of the "coefficient of rotation" of equation 1. Since reactance voltages are opposite in phase to induced emf, the minus sign is attached to M_{daqu} to express the correct time phase of the speed reactance voltage according to equation 39. The same sign is given to M_{duqu}. With similar reasoning, M_{qadu} and M_{qudu} are given positive signs.

Now the complete set of fundamental equation of voltages of the component windings for the cross-field theory analysis may be written as

$$\begin{aligned}
v_{da} &= L_{da}pi^a + M_{duda}pi^u \\
v_{qa} &= L_{qa}pi^a + M_{quqa}pi^u \\
v_{du} &= M_{dadu}pi^a + M_{qadu}i^a p\theta + L_{du}pi^u + \\
&\qquad M_{qudu}i^u p\theta \\
v_{qu} &= M_{qaqu}pi^a - M_{daqu}i^a p\theta + L_{qu}pi^u - \\
&\qquad M_{duqu}i_u p\theta
\end{aligned} \tag{40}$$

Equations 40 correspond to equation 1 where L_{da}, M_{duda}, etc., are given in equation 2.

Equations 40 may be added in pairs and reduced to

$$\begin{aligned}
v_a &= (L_{da}+L_{qa})pi^a + (M_{duda}+M_{quqa})pi^u \\
v_u &= [(M_{dadu}+M_{qaqu})p - (M_{daqu} - \\
&\qquad M_{qadu})p\theta]i^a + [(L_{du}+L_{qu})p - \\
&\qquad (M_{duqu}-M_{qudu})p\theta]i^u
\end{aligned} \tag{41}$$

This corresponds to equation 5.

Appendix IV. Short-Circuit Analysis of Single-Phase Alternator

Equation 30 in the usual form of differential equations becomes

$$\begin{aligned}
V_a &= r_a i^a + p[(L_0'+L_2\cos 2\theta)i^a] + \\
&\qquad p(M\cos\theta i^u) \\
V_u &= p(M\cos\theta i^a) + r_u i^u + p(L_u i^u)
\end{aligned} \tag{42}$$

This is the fundamental equation of a general 2-winding machine and may be applied to single-phase alternator.

To evidence the infinite harmonic reflections on both stationary and rotating members of the single-phase alternator as predicted by many authors, a short circuit at the armature terminals is analyzed. Since a short circuit at armature terminals is equivalent to applying suddenly a negative voltage $-v_a$ to annul completely the applied voltage v_a, the alternating components of short-circuit currents can be approximately solved by the "constant-linkage theorem" as follows:

$$\begin{aligned}
-v_a &= p[(L_0'+L_2\cos 2\theta)i^a] + \\
&\qquad p(M\cos\theta i^u) \\
0 &= p(M\cos\theta i^a) + p(L_u i^u)
\end{aligned} \tag{43}$$

After integration equation 43 becomes

$$\begin{aligned}
V[\cos\alpha - \cos(\theta+\alpha)] &= (L_0+L_2\cos 2\theta)i^a + \\
&\qquad M\cos\theta i^u \\
0 &= M\cos\theta i^a + L_u i^u
\end{aligned} \tag{44}$$

where

$$v_a = V\sin(\theta+\alpha) \tag{45}$$

whence

$$i^a = \frac{V}{\omega}\;\frac{\cos\alpha - \cos(\theta+\alpha)}{L_0+L_2\cos 2\theta - M^2\cos^2\theta/L_u}$$

$$i^u = \frac{MV}{\omega}\;\frac{\cos\theta[\cos(\theta+\alpha)-\cos\alpha]}{L_u(L_0+L_2\cos 2\theta) - M^2\cos^2\theta} \tag{46}$$

When this equation is developed, both even and odd harmonics will appear. In the classic work by Doherty and Nickle,[11] i^u was not considered when the constant linkage theorem is applied. If cylindrical rotor type is dealt with, L_2 in equation 45 becomes zero, which conforms to the result of Lyon.[12]

Objectives and General Description of the Type-P1 Carrier System

R. C. BOYD
ASSOCIATE MEMBER AIEE

ALTHOUGH carrier has been used successfully to provide trunks in the Bell System for more than 35 years, it has not been economically feasible to apply carrier telephone techniques extensively to the rural telephone plant up to the present time.

The technical and economic problems associated with providing telephone service to subscribers in rural areas has long been one of the most difficult problems facing the telephone industry. The widely scattered locations of subscribers in rural areas have led to a large number of rural telephone routes with only a few subscriber lines per route. This has precluded the use of large cables on any one route as would be economically attractive in urban areas. The extensive use of carrier has not been feasible because the distances from the rural subscribers to the central office are in the 5- to 25-mile range in which carrier has not been generally economical in the past.

The two lines of attack which were taken on this problem were to reduce the cost of telephone plant through less expensive small cables and open-wire plant,[1] and to provide an economically attractive carrier system designed to meet the particular needs of rural carrier telephone service.

The *M1* system which has been in use since 1946 was the first successful Bell System effort to meet the need for more economical rural telephone service by carrier methods. It was developed primarily for application to commercial power lines but has also been used to a lesser extent on telephone lines. At present, there are roughly 10,000 subscribers served by *M* carrier channels.

Experience with the *M1* carrier system has indicated that carrier systems can be installed and maintained by exchange area forces with proper training and equipment. In addition, the background provided by the *M1* carrier indicated the direction for future development work on a rural subscriber carrier system.

The use of rural telephone lines indicated that in order to reduce the cost of line treatment it would be desirable to use frequencies lower than the 150- to 450-kc range used for the *M* carrier. In addition, lower frequencies would make it possible, from a crosstalk standpoint, to apply more than one system per rural line, which is often desirable in areas of rapid growth.

Inherent in the use of a rural subscriber system, such as the *M* carrier system, was the fact that a remote terminal must be placed on a pole or on a subscriber's premises. This created the need for low-power drains in the carrier equipment. The operating companies indicated the necessity of providing stand-by or primary battery power for the power supply of such a carrier terminal to insure reliable service in the face of commercial power failures.

In addition to the requirements for a rural subscriber system derived from the experience with the *M* carrier system, there were two other basic requirements: (1) to provide a grade of service equal to or better than that now available on long rural lines; and (2) to make available the several types of signaling required on Bell System multiparty lines served by manual or dial offices. However, the most important requirement of such a carrier system was that in addition to meeting the technical requirements imposed by the rural environment it also had to prove in *economically* over conventional physical telephone plant in the difficult 5- to 25-mile range.

The application of this carrier system background to the special technical and economic needs of rural telephone service has resulted in the development of the type *P1* rural subscriber carrier system. It is a fully transistorized system consisting of independent 2-way carrier channels applicable in increments of one to four at a time. Each channel is capable of providing single or multiparty (up to eight parties) exchange service to rural subscribers comparable to that provided by voice-frequency methods. The system will be applicable to existing and new lines utilizing combinations of fine-gauge exchange cable and copper or steel open-wire, repeaters to be used where necessary. Several systems can be used on a single pole line, the number depending on the open-wire line characteristics.

Development Background

To illustrate the development background of the *P1* system, the reasons behind the choices of a number of the parameters of the system are discussed in the following. Because of the stringent economic objectives of the system, cost was a paramount consideration in most of the items.

TRANSISTORS VERSUS VACUUM TUBES

Transistors were chosen for use in the *P1* system because they are low-voltage lower power devices as compared to the higher d-c power requirements of vacuum tubes suitable for transmission circuitry. Also, transistors are expected to be inherently longer life devices than vacuum tubes, thus contributing to reduced maintenance costs.

It was appreciated that the problems of transistor production and resulting component reliability were not completely resolved at the time the decision was made but it was felt that they showed sufficient promise to justify exploration of their possible use. This decision opened the way for use of primary battery power plants or those operated from commercial power with miniature storage battery reserve as described in another paper,[2] thus greatly reducing the cost of providing power at remote terminal and repeater locations.

LOW-VOLTAGE PROTECTION

With the use of transistors and the associated low-voltage power supplies, it became possible to use other low-voltage components in the carrier circuitry. This gave rise to the need for supplementary protection of such components from voltage surges on the line below those for which conventional carbon blocks afford protection. Voltage-limiting diodes offered a means of providing such protection. Development work was started to find and utilize diodes which could withstand voltages up to 1,000 volts.

FREQUENCY RANGE AND METHOD OF MODULATION

It is difficult to divorce the considerations leading to the choice of the carrier frequency range from those affecting the choice of modulation in the carrier system.

Paper 56-240, recommended by the AIEE Wire Communication Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 20, 1955; made available for printing January 4, 1956.

R. C. BOYD is with Bell Telephone Laboratories, Inc., New York, N. Y.

The frequency range was blocked out by a number of factors.

Cost considerations required that the carrier frequencies be kept above the voice-frequency range. If carrier extended into the voice range, the voice-frequency circuit would be lost on a carrier pair. Then one of four carrier channels applied to that pair must be used to replace it. Thus, the addition of four carrier channels to a pair would yield a net gain of only three channels. This in turn would increase the net cost per gained channel. Filter costs determined how close to the voice-frequency band the carrier frequency range could be placed.

Crosstalk considerations restricted the carrier frequency range to below about 100 kc in order to reduce the cost of line treatment and rearrangement of pairs on existing rural lines. By using this frequency range it appeared possible to apply more than one carrier system to an open-wire line. The rapid rise in attenuation with frequency of steel wire used on rural lines also dictated that the range of carrier frequencies be kept low.

As a result of these two sets of considerations, development work on the *P1* carrier system was concentrated in the 8- to 100-kc range. At the time the choice was made, amplitude modulation of the carrier frequencies was chosen over other forms of modulation because of the simpler terminal circuitry and equipment. The use of amplitude modulation coupled with the compandors discussed in a later section was felt to compensate for possible transmission advantages which could be obtained by using angular modulation (frequency or phase) with a large modulation coefficient.

Cost was again a major factor in the choice between double-side-band and single-side-band amplitude modulation. Double side-band was chosen because of easier filter requirements. Although single-side-band modulation would give more efficient use of the frequency spectrum, it was ruled out because of the problems of obtaining necessary carrier power at the receiving terminal, and a possible high cost of filtering and circuitry to cut apart the carrier and the unwanted side-band.

Studies of growth on rural lines indicated that a system giving three or four channels on one pair of wires in addition to the physical circuit should be sufficient if several systems could be applied to a given open-wire line. It was, therefore, possible to space eight carriers at 12-kc intervals from 12 to 96 kc.

The unusually wide carrier spacing of 12 kc was adopted in order to minimize filter costs. Since the remote terminals are distributed along the line, it is not practical to use group modulation to accomplish filtering in the most efficient frequency range. Instead, filtering is done at line frequencies. This results in the use of rather large inductors and capacitors for some channels, thus placing a premium on the simple filter structures which wide spacing permits.

Fig. 1 shows the frequency plan for the *P1* carrier system. The staggered frequency arrangement was provided to improve crosstalk performance between systems, where necessary. The application of the three different frequency arrangements is discussed in detail in another paper.[3]

The use of frequencies spaced at 12-kc intervals for the *P1* system will create problems if applied to lines used by toll carrier systems which have 8-kc spacings. However, the cost advantages of the filters for 12-kc spaced carriers in general more than offset these potential problems.

System Levels and Carrier Line Loss

The carrier-frequency output power of the transistorized transmitting amplifier in the terminals was set at 6 decibels above 1 milliwatt. This was determined by the state of the transistor art, d-c power limitations at remote terminals, and co-ordination considerations. Because of the loss in the secondary protection circuitry, this became 4 decibels above 1 milliwatt at the carrier line terminals. Span pads were provided in the terminals and repeaters for use as required for level co-ordination.

This output level coupled with noise and crosstalk considerations indicated that a 30-decibel carrier line loss between the terminals would be possible. A survey of existing and planned Bell System rural telephone lines indicated that substantial amounts of entrance cable and open wire would be encountered in potential carrier channel layouts. Calculations of carrier frequency loss of these facilities indicated that carrier repeaters would be required between the terminals in order to serve the more remote subscribers. Fig. 2 shows an example of such data for one area studied.

Compandors

Compandors were incorporated in the *P1* system design because their added equipment cost was considered to be more than offset by their several advantages. The crosstalk and noise advantage provided by their use reduced the need for expensive line treatment to reduce crosstalk. In addition, it permitted lower receiver carrier levels to be used, thus increasing the permissible carrier line loss. Compandors also eased the requirements on terminal and repeater filters, thus reducing filter cost.

A number of different compandor configurations were studied including instantaneous and tone-controlled compandors before it was decided to use a simplified version of the compandor incorporated in the type *N* and *O* carrier systems.

Regulation

Channel regulation was deemed necessary to provide satisfactory transmission performance and to keep maintenance adjustments to a minimum. The regulation was designed to compensate for daily and seasonal carrier circuit net loss variations caused by changes in line attenuation with temperature. It would be desirable to have the terminal regulation range equal to the 30-decibel loss permitted between terminals to ease engineering layout considerations. However, cost considerations led to a smaller regulation range with span pads used as required by system layout to adjust the received carrier to within the regulation range.

Repeater regulation will be required as an option where variations in line loss exceed the terminal regulating range. It will usually be necessary on systems employing more than one repeater in order to control noise performance. Repeater regulation in the direction of transmission from central office to remote terminal will be controlled by the total carrier power of the one to four channels working in one system. In the opposite direction the repeaters will regulate on a carrier frequency pilot, because the channel carriers are not always present in that direction of transmission. The pilot frequencies are shown in Fig. 1. Span pads were also provided in the repeater to adjust the received carrier where necessary.

Signaling

The need to transmit subscriber signaling information over a carrier channel required the development of means of passing dialing and supervision signals toward the central office. It also required passing ringing information to the remote terminal for the types of multiparty ringing generally used in the Bell System. At that location standard 20-cycle ringing signals had to be recreated to ring the subscriber instruments. Carrier on-off signaling was chosen to transmit dialing and supervision signals because of the ease of implementing it and because of savings in d-c power drain of the remote terminal achieved by transmitting the carrier toward the central office only during the off-hook condition.

In-band frequencies were chosen to encode ringing information for transmission over the carrier channel because of the substantially lower cost of in-band filters as compared to those required for out-of-band transmission.

Summary of System Parameters

The system features evolved during the planning and development of the *P1* carrier system may be summarized as follows:

Transistors:

Diode low-voltage protection.

Frequency range:

9–99 kc.
Channel bandwidth 230 to 3,000 cycles at 5-decibel points.

Amplitude modulation—double side-band.
Three to four carriers per pair of conductors:

Staggered or normal arrangement.
Several systems per open-wire line.

System levels:

6 decibels above one milliwatt at transmitting amplifier output.
4 decibels above one milliwatt at carrier line terminals.

Carrier line loss:

30 decibels between terminals or repeaters.

Compandors:

Integral part of terminals.

Regulation:

15 decibels in terminal.
10-decibel option in repeaters.

Signaling:

Dialing and supervision by on-off carrier.
20-cycle ringing via in-band tones.

Discussions of considerations leading to design choices in areas of circuitry, equipment, and power are presented in other papers.[2,3]

Line Networks

The proposed application of *P1* terminals and repeaters to rural lines created the need for several types of line networks or filters. Low-pass filters were required to isolate bridged subscribers' instruments from the carrier line and to reduce their bridging loss to passing carrier frequencies. High-pass filters were required to isolate the voice-frequency extensions of different carrier channels from each other or from the physical circuit. Other networks were required at the junction of the cable and open-wire pairs. Small cross-arm-mounted networks were designed using the simplest possible configurations in keeping with the transmission and economic objectives of the *P1* system. Their use and equipment aspects are discussed further in other papers.[2,4]

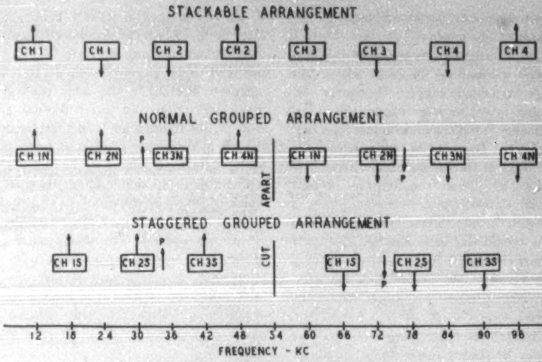

Fig. 1. Frequency allocation chart

P—Pilot frequency for repeater regulation

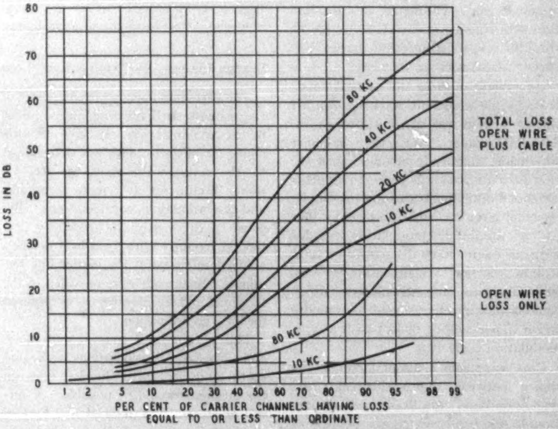

Fig. 2. Distribution of cable and open-wire losses for potential carrier channels

Maintenance

The prospect of the extensive use of the *P1* carrier system in the subscriber telephone plant led to the requirement that simple methods and test equipment be available for installing and maintaining the system. It was proposed that a single, compact test set be developed with options for battery or a-c operation, and that testing methods be devised to permit a craftsman with a minimum of training to isolate a carrier-line trouble to a unit of the system, such as a carrier terminal, and to adjust or replace that unit. Further isolation of trouble within a replaced unit could then be done most efficiently at a central test point. Alarms were not built into the *P1* system because it was felt that trouble reports should be received and analyzed at the exchange office test desk as is now the practice for physical rural lines.

Vol. 7
Pt. 1
1956

Present Status

Many of the circuits, components, and equipment arrangements incorporated in the *P1* carrier system had not been used or tested before. Therefore, experimental models of the carrier channel terminals, repeaters, line networks, and testing equipment were built and tested in the laboratory and in a representative rigorous rural environment at Americus, Ga.

The results of these tests were encouraging enough to justify the development of the *P1* carrier system for manufacture by the Western Electric Company. It is expected that the first channel terminals will be available to the Operating Companies in the Bell System in the second quarter, 1956. Repeaters will follow probably during the fourth quarter, 1956.

OTHER APPLICATIONS

The *P1* carrier system has been developed to provide an economical method of serving new rural telephone subscribers on new or existing rural telephone lines. It may also be used to give existing rural subscribers a higher grade of service, e.g., changing the service from 8-party semiselective to 4-party full selective ringing. In addition, the system will make it possible effectively to extend the ringing ranges of existing offices without adding other expensive switching equipment.

In addition to use as a rural subscriber system, the *P1* carrier system shows promise of providing a transmission facility for use on exchange area trunks. A new trunk signaling system is being developed for use in conjunction with the transmission portion of the *P1* carrier system, which is expected to be available for Bell System use early in 1957.

Conclusion

A study of the problem of providing economical rural subscriber telephone service indicated the need for an economical carrier system which could be operated on rural open-wire lines. The *P1* carrier system has been designed to meet that need by providing a flexible facility for adding a number of subscribers channels to an existing rural line with a minimum of line treatment.

Power Supplies for the Type-P1 Carrier System

D. H. SMITH
MEMBER AIEE

Synopsis: Low first cost and annual charges, good voltage regulation, high reliability, and low maintenance were major objectives guiding the choice of power supply design for the type-*P1* (rural) carrier system recently developed by Bell Telephone Laboratories. A study of conventional designs revealed that new techniques would be necessary to realize these objectives. This paper describes how the use of semiconductor devices, the employment of unconventional approaches to power supply packaging, and the development of a new type of lead-acid storage battery influenced design decisions to the end that the major objectives were realized.

EARLY in the development program[1] of the type-*P1* (rural) carrier system, engineering studies revealed that, for several reasons, the power supply problem would be difficult to solve. First, there was the large relative cost of supplying a small amount of power in the order of 1 watt. Second, there was the requirement for 1-per-cent or better voltage regulation under extreme environmental conditions. Third, there was the need for high reliability in locations remote from the telephone office and, concurrent with this, the necessity for reducing maintenance to a single service call per year. This paper describes how a power plant was developed to meet all four objectives.

Power requirements for the carrier system are quite low. The central office terminal draws about 75 ma (milliamperes) at 22 volts from the standard office power plant. A remote terminal averages about 50 ma at 22 volts, but the load varies from a quiescent current of about 30 ma to almost 1/2 ampere during the ringing interval. A repeater, serving up to four carrier channels,[2] requires about 150 ma at 22 volts. In addition, each equipment draws a few ma at 16 volts for bias. A remote power supply must operate satisfactorily in an ambient temperature of from −40 to +140 F (degrees Fahrenheit).

Commercial 60-cycle power is available in almost all rural areas in this country and the power plant described here is designed to operate from this source. Long secondary feeders are common, however, and some form of power reserve is necessary. When 60-cycle power is not available, a primary battery is furnished as an alternative to the a-c operated supply.

The High Cost of Low Power

The cost of a telephone power plant generally decreases with decreasing capacity but, even so, the cost per watt-hour generally goes up as the capacity goes down. Experience has shown that a conventional design to deliver 1 or 2 watts costs nearly as much as one to deliver 10 to 20 watts. One yardstick often used is to relate the cost of the telephone power plant to that of the equipment which utilizes the power. This ratio can vary from 5 per cent for very large multiunit central offices to 40 or 50 per cent for very small installations. The cost objectives of the rural carrier system were such that past experience had to be bettered by at least 2 to 1. This was realized by using semiconductor devices for power rectification and control, the development of a new type of lead-acid storage battery to meet severe temperature conditions, and efficient equipment packaging.

For output ratings in the power range of 1 or 2 watts, prime sources tend to be even more expensive than conversion of commercial alternating current and pro-

vision of a reserve storage battery. Storage batteries on a removal-for-charging basis, dry cells, wind generators, small internal combustion engines, and thermocouple generators were considered but, in each case, the economics favored an a-c operated rectifier with battery reserve.

The Power Plant Circuit

The rectifier, Fig. 1, uses semiconductor diodes *CR1* in a full-wave bridge circuit. In the first models, germanium diodes are furnished, but it is expected that these will be replaced by silicon in the near future. The output of *CR1* is fed to a transistor shunt regulator *Q1* through a ballast resistor *R1*. *Q1* is controlled by a transistor network (enclosed by the dashed lines). The operation of the network is to increase the emitter-base current of *Q1* when the battery voltage is too high and to decrease the current when the battery voltage is too low. An increase in the emitter-base current of *Q1* causes an increase in the collector-emitter current, an increased voltage drop in ballast resistor *R1*, and a subsequent reduction in battery voltage until the regulated value is reached. Transistor *Q1* is a p-n-p device having a maximum collector dissipation rating of about 2 watts at 140 F, when mounted on a heat-dissipating plate or chassis.

The heart of the control network is a varistor *CR3* which serves as a voltage reference standard because of its very stable voltage drop of about 6 volts over a wide range of temperature and current. The properties of this diode have been covered previously.[3] The emitter current of transistor *Q3* flows through the reference diode, and the base-to-emitter voltage is the difference between the voltage drop across terminals 2 and 3 of potentiometer *P1* and the reference voltage across *CR3*. With *P1* adjusted so that the base of *Q3* is slightly positive with respect to the emitter, an increase in the battery voltage will increase the base-to-emitter voltage and, thus, the base current of *Q3*. The collector current of *Q3* will then increase and, since part of it also flows through the emitter-base circuit of transistor *Q2*, through a similar action the collector current of *Q2* will increase. This in turn increases the collector current of transistor *Q1* which reduces the battery voltage, as covered previously. The total loop gain in the regulator circuit is about 35 decibels, and an over-all regulation accuracy of ±1 per cent is maintained over a temperature range of −40 to +140 F, input voltage variation of ±5 per cent, and load current range of 30 to 175 ma. The high loop gain also provides most of the ripple filtering necessary.

Above a 175-ma load, the load voltage decreases linearly to approximate a constant-current characteristic. Such protection is required when battery reserve is provided. Normally the battery "floats" across the load, drawing less than 1 ma or so at the regulated voltage. It undergoes a momentary discharge when load currents in excess of 175 ma are drawn, such as during the ringing interval. This energy is quickly restored, however. If a-c power fails, the battery supplies all the load current until it is fully discharged. Upon the return of a-c power after a prolonged outage, the battery tends to draw a very high current, far beyond the capabilities of the rectifier. The current-regulating action limits this recharge current to a safe value. This action is explained by reference to Fig. 2, the general equivalent circuit of the power plant.

In Fig. 2(A), *R1*, R_{Q1}, and R_N are respectively the regulating or ballast resistor, the shunt resistance of the emitter-collector circuit of transistor *Q1*,

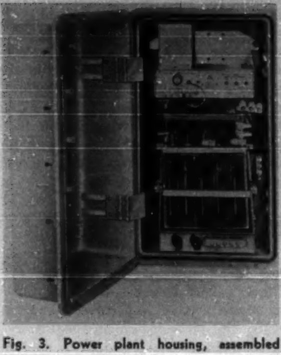

Fig. 3. Power plant housing, assembled

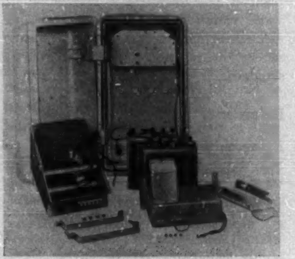

Fig. 4. Power plant housing, components removed

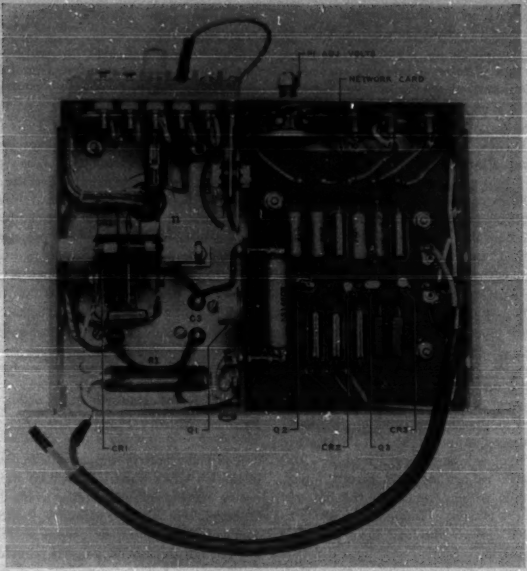

Fig. 5. Bottom view of rectifier chassis

and the equivalent resistance of the network components. The current drawn by the network i_n can be considered constant and part of the load current i_1. The load characteristic of the rectifier is represented by the heavy line in Fig. 2(B). At minimum load, R_{Q1} is very low and enough current i_2 is shunted around the load to drop the voltage from E_0 to the regulated value of 22 volts. As the load increases, R_{Q1} is made to increase, thus reducing I_2 and, in effect, transferring more and more of i_1 to the load. At full regulated load, determined by the intersection of the load line (slope $= R_1$) and the desired value of regulated voltage (22 volts), transistor *Q1* cuts off i_2. Further increase in load current causes a reduction in load voltage, as shown. *R1* can be varied within rather wide limits at the designer's discretion. An increase in *R1* will provide a sharper current cutoff but will raise the required transformer secondary voltage. The maximum power dissipation of *Q1* also will be increased.

The shunt-regulating circuit of Fig. 1 was chosen for this application because the current-limiting feature described in the foregoing is an inherent characteristic. A series-regulating circuit would be more efficient, but the additional circuitry required to provide current-limiting in a series regulator would add expense and complexity which could not be justified by the relatively slight power saving.

A final feature of interest in the rectifier is the provision of regulated base bias potential for the carrier terminal circuit. In Fig. 1, *CR4* and *R12* form a potentiometer across the 22-volt output. *CR4* is a 6-volt reference voltage diode similar to *CR3*, and acts as a second shunt regulator furnishing a potential always 6 volts more positive than the collector voltage.

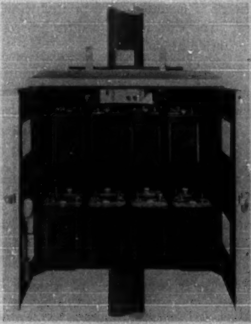

Fig. 6. Alternate power supply using primary batteries

The Battery

The battery weighs about 10 pounds and stores sufficient energy when fully charged to operate a carrier terminal about 4 days and a repeater about 2 days. In addition to its function of providing reserve during a-c power failure, the battery furnishes additional current required by the load during ringing intervals. These intervals are short and do not discharge the battery appreciably. This feature permits size reduction of the power transformer and permits conservative operation of the rectifying diodes and transistor *Q1*.

The electrolyte has a specific gravity of 1.300 or about 7 per cent higher than conventional telephone storage batteries. An excess of electrolyte is provided so that, when the battery plates are fully discharged, the electrolyte still has acid content to prevent freezing at lowest temperatures. Ordinarily, the higher acid content would increase local action and shorten the life of the battery, but a new type of battery plate grid, made of a lead-calcium alloy, inhibits local action so that a service life of about 10 years is expected.

Power Plant Packaging

The a-c operated power plant is housed in a pole-mounted cast-aluminum box similar to that provided for the carrier terminal, thus taking advantage of the lower cost with a single design. The box is about $23^{3}/_{4}$ inches tall, $12^{1}/_{2}$ inches wide, and $10^{5}/_{8}$ inches deep. Ready for operation, the plant weighs about 50 pounds. The power plant is shown in Fig. 3. At the top of the housing is the rectifier. The battery, consisting of two 5-cell plastic jars, produced in quantity for other applications, is arranged on "steps" so that the electrolyte level can be observed readily. Removable rubber stoppers permit filling the cells without removing the battery from the housing. Immediately beneath the battery are the load fuses and terminal strip.

In Fig. 4, the components of the power plant have been removed from the box and, in Fig. 5, a bottom view of the rectifier is given. The regulating control network is mounted on a printed-wiring card. The card is designed for low-cost mechanized assembly.

Reliability and Maintenance

The objectives of high reliability and low maintenance were weighed carefully against first cost throughout the development of the power plant. Transistors were operated at conservative levels for maximum life. Resistors and capacitors were chosen on the same basis. The storage battery was made slightly oversize to lengthen the maintenance interval; present estimates are that water need be added only at intervals of once a year or longer. In the network circuit, a reference diode having a slightly positive temperature coefficient is used to compensate for the small negative temperature coefficient of the emitter-base junction in transistor *Q3*. Thus, the necessity of a seasonal readjustment of the output voltage is eliminated.

Primary Battery Plant

A primary battery supply will be used in the few cases where commercial alternating current is not readily available. It consists of alkaline primary (nonrechargeable) batteries, as shown in Fig. 6. Enough battery capacity is provided to operate a remote terminal for about 2 years and a repeater for about 1 year. Specially designed to operate in extreme temperatures, the battery uses a caustic alkali as an electrolyte, a zinc negative electrode, and a carbon positive electrode, and is oxygen-depolarized. The batteries are shipped dry and water is added to liquify the dry electrolyte on the job. After the battery is fully discharged, a new battery is installed. The battery plant, installed and ready for service, measures $35^{1}/_{2}$ by $35^{1}/_{8}$ by 14 inches, and weighs about 350 pounds. It is more expensive, both in first cost and annual charges, than the a-c operated plant.

Conclusion

The a-c operated power plant described has been developed for the type *P1* (rural) carrier system. When operated at 50 ma average load current, and 22 volts, the plant maintains the battery at full charge and provides a reserve against failure of primary power. The plant is pole-mounted, is insensitive to wide variations in line voltage and ambient temperature, and will have a long service life consistent with Bell System standards.

Discussion

Charles F. Crocker (General Electric Company, Lynn, Mass.): This paper is a very good presentation of what was done but I would like to see the reasons for doing it this way. Was any special selection necessary to get transistors of suitable characteristics for this unit? Is there any desirable range of α for *Q1*, *Q2*, and *Q3*? Because the circuit is direct-coupled throughout, the characteristics of *Q3* would seem to be critical. What I_{co} limits give satisfactory operating conditions for this stage? I would also like to see detailed characteristics for the power transistor *Q1*, particularly collector current, voltage rating, and power gain. It is gratifying to see the application of semiconductor devices to a product that must be reliable. This power supply uses several types of units with large savings in power and space and apparently an increase in reliable life over conventional equipment.

There is still a lack of acceptance of the newer types of these products by some sections of industry. I should be interested in seeing the data on the several transistor types and the junction diode types that led to their adoption on a basis of increased reliability. There are probably many people, such as myself, who are very concerned about reliability of electronic equipment but are not able to carry on any significant life testing. Mr. Smith, being associated with an organization that has done so much fundamental work on transistors, and who obviously knows what reliability of equipment means, may be able to give us some very valuable data.

There are many ways that such data could be presented, but I would like to suggest a few that would be of much interest to me. These are service failure rates in the following classes: 1. amount of derating from rated values of currents and voltages; 2. initial parameters such as α and I_{co}; 3. time in service; and 4. ambient operating conditions.

D. H. Smith: Mr. Crocker's comments relate to one of the most interesting design problems in many circuits using semiconductors, namely, that of the interdependence of circuit functions and device characteristics. Arrangements that appear to be straightforward in the notebook stage often become almost unrecognizable as the designer adds functions to overcome such variations as transistor current gain, transistor leakage current, and rectifier forward drop. Unfortunately, the treatment of this subject is not within the scope of the present paper.

During the development of the regulator under discussion, however, we were fortunate that semiconductor device development had already reached the point where manufacturing and operational variations in the parameters were well characterized. Circuit analysis, based on the range of current gain and collector saturation current for standard Western Electric transistors, indicated satisfactory circuit performance under specified environmental, load current, and line voltage conditions. The general statement can be made that, in production, special selection should not be required for any semiconductor components, nor should special transistor designs be necessary for the regulator circuit described.

The reliability question cannot, of course, be completely resolved until considerable operating experience is obtained. During the field trial of the *P1* carrier system, very good reports were received after initial circuit shakedown. Some data show, for example, that, of 90 semiconductor diodes employed in lines as lightning protectors, only one gave evidence after 2 years of operation of adverse drift in characteristics. Our observations of four regulated rectifiers of the type described in my paper, installed and operating in the Georgia field trial for about the same period of time, revealed no failures caused by transistors or diodes after initial shakedown.

Detailed life data in the form suggested by Mr. Crocker would be welcomed by circuit designers, and manufacturers should be encouraged to furnish life data on the device data sheets. Until this becomes a general practice, it appears that the design engineer must continue to rely on the integrity of the device manufacturer, together with judgment obtained from assiduous development experience.

Circuit and Equipment Descriptions of Type-P1 Carrier System

E. H. PERKINS
NONMEMBER AIEE

THE broad objectives and application principles for the *P1* carrier system opened a new field of use for carrier equipment. However, to exploit this field, several new requirements had to be met. These demanded that the system be of substantially lower cost than any before, that it use only a small fraction of the power, yet maintain the quality associated with a carrier system.

These objectives have been met. Carrier circuitry has been devised to use transistors which consume only a fraction of the power required by vacuum tubes. Plug-in equipment concepts have been worked out so that the manufacturing and handling of the apparatus is greatly improved, and new and better component parts have been developed to fulfill circuit and equipment needs.

This system is generally similar to the recently designed type-*N* carrier system. It utilizes double-side-band transmission which is appreciably simpler and cheaper than single-side-band transmission. It has compandors to liberalize crosstalk coupling requirements and to improve the signal-to-noise ratio. It uses the stackable arrangement of channels, with each channel a complete entity, but with the ability to stack channels in frequency to form a complete system.

This system, however, has important differences from previous systems. Whereas previous systems have been for use between central offices where both terminals were identical, this system is for use between a central office and a subscriber. This use requires terminals with somewhat similar transmission circuits but completely different signaling circuits. The signaling is further complicated by the variety of types of service offered to rural subscribers. Thus, the terminals for this system are specifically designed to the needs of the respective ends and are designated as the central office terminal and the remote terminal.

A detailed analysis of this system readily divides into the aspects of transmission, equipment, and component features. The system transmission may be further divided into terminal and repeater considerations.

Terminal Transmission

The transmission block schematic for the terminals is shown in Fig. 1. The voice circuit at either end of the system connects to the carrier circuit through a secondary protection circuit and resistance hybrid circuit. The protection offered by the usual carbon blocks was adequate for vacuum tubes but transistors require a much lower value. This additional protection is obtained by using the reverse-voltage breakdown characteristic of newly developed silicon diodes.

The hybrid circuit in turn connects to the compandor and signaling circuits. In the transmitting direction the carrier portion of the terminal consists of a modulator with associated carrier oscillator, a transmitting amplifier with level adjusting pads, and a transmitting filter. In the receiving direction there is a receiving filter, a level adjusting pad, and a receiving amplifier-demodulator. This carrier portion of the terminal is connected to the line through an impedance-matching transformer and secondary protection equipment.

The compandor though performing the same function as for previous systems employs different circuitry. The compressor uses a backward-acting shunt variolosser. The variolosser employs silicon diodes controlled by its rectified output signal, integrated over a syllabic period. As this variolosser operates at very low signal levels, a 2-stage feedback transistor amplifier is used to amplify the voice signals sufficiently to activate the modulator.

The 2-stage transistor-type amplifier is a basic building block of the system, and it is referred to as the *P*-terminal 2-stage amplifier. It is designed as a voice amplifier for the compressor and expandor and as a carrier amplifier for the transmitting and receiving amplifiers. A circuit drawing of this transmitting amplifier is shown in Fig. 2. It uses n-p-n type of transistors, coded *4B*, for the voice-frequency amplifiers and *4C* transistors for the carrier amplifiers. The first transistor is connected as a common collector and the second as a common emitter. By using them in this manner it is possible to employ the same type of transistor in both stages. Feedback is obtained by using high-side hybrid coils at both the input and output of the circuit in much the same manner as for vacuum-tube circuits. One significant difference is that in this transistor circuit only the second transistor introduces a 180-degree phase shift. This permits both input and output coils to return to a common ground as in a 3-tube vacuum-tube circuit and thereby avoid the circuit complications of a 2-tube circuit where one of the coils must float off ground.

The control signal for the variolosser is derived from the output of this amplifier and is in turn amplified by a 2-transistor feedback amplifier before being rectified. The characteristics of the compressor and associated expandor are shown in Fig. 3.

The modulator is a silicon diode ring with balance to eliminate the voice components. As this also effectively eliminates the carrier, it is reintroduced

at the desired level for transmission at a hybrid connection following the modulator.

The carrier oscillator is a 2-transistor circuit. A *4C* transistor is used in a common-emitter circuit with a tank circuit in the collector circuit. Feedback is obtained from the tank circuit to a transformer to the base of the transistor. The output is obtained from the tank circuit through another common-emitter *4C* transistor as an amplifier.

The transmitting amplifier is used to raise the side-band level to the nominal value of −8 decibels (db) for transmission. It provides about 50 db of gain and has a characteristic as shown in Fig. 4.

The transmitting and receiving filters serve to connect the several channels of a system to the line. They pass only the frequencies desired for their particular channel, and prevent unwanted modulation products from the channel modulators from reaching the line and becoming crosstalk into other channels. And, vice versa, they exclude unwanted frequency signals from the demodulator where they would be demodulated as crosstalk. These filters and the carrier oscillators are the only frequency-conscious elements in the system. Typical loss characteristics for them are shown in Figs. 5 and 6.

The output pad permits the level of the transmitted signals to be adjusted for proper line co-ordination. The input pad permits the received signals to be adjusted for varying line losses.

The receiving amplifier is a 3-stage transistor regulating amplifier. It uses a *4C* transistor in a common-emitter circuit for the first stage followed by a modified *P*-terminal 2-stage amplifier. Feedback is necessary on the last two stages only to provide adequate control of the output impedance and the amplifier modulation. The input stage has sufficiently low signal level so that modulation is not a problem. The input impedance is also under sufficient control without resorting to the difficulties of a 3-stage feedback circuit. Because of the addition of the third transistor, the feedback is of the shunt type at the interstage between the first and second transistors.

The regulation in the receiving amplifier is of the backward-acting type. It uses silicon diodes at the amplifier input in a shunt-type variolosser. These diodes are activated by direct current from the control circuit. The control power is derived from the output of the receiving

amplifier, amplified by a common-collector transistor amplifier and rectified by a voltage-doubler circuit. The reference to determine the regulator level is obtained from a reverse breakdown silicon diode of about 6 volts. The level of circuit regulation is controlled by potentiometer adjustment across the reference diode.

The demodulator is a bridge-type silicon diode rectifier. This rectifier is followed by a loss-pass filter to reject all but voice-frequency signals.

The expandor is of the forward acting type which derives control of the variolosser from the input signal. This signal is amplified, rectified by a voltage doubler, and bucked against a potentiometer-adjusted portion of the system battery. The variolosser uses silicon diodes in a series-type circuit. The variolosser is followed by a 2-transistor feedback amplifier similar to that used in the compressor to provide the necessary voice signal level.

The transmission qualities of this system are comparable to those obtained with toll-type carrier systems. The channel frequency characteristic is shown for each direction of tranmission in Fig. 7. Shown also for comparison are the limits prescribed for toll-system quality, which indicate this system meets toll requirements. The talking circuit has the good signal-to-noise ratio customarily found in carrier circuits. In service these channels will be found to be very quiet compared to the normal voice-frequency channels. The lower noise level is inherent in the use of carrier frequencies for transmission and is also aided more than 20 db by use of compandors.

Signaling

The signaling requirement for the system is that it shall fit into a voice-frequency circuit without needing any change of the existing signaling equipment at either end. This means that the central office terminal shall be activated by 20-cycle ringing which the remote terminal shall reproduce, and that the remote terminal shall be activated by dial pulsing, which the central office terminal shall reproduce. Thus, the two terminals have completely different signaling circuitry, and each direction of signaling is entirely separate. These terminals are shown in block schematic form in Fig. 8.

Central Office Signaling

The signaling by the central office is accomplished as in a voice circuit by putting a positive or negative d-c bias voltage superimposed with a 20-cycle a-c tone on either tip or ring to ground of the transmission pair. The different combinations of these variables provide the necessary control to select any one of four subscribers and is the information that must be reproduced by the remote terminal for transmission to the subscriber's line.

2,500 and 1,150	ring party −
2,500 and 1,750	tip party −
2,500, 1,750, and 1,150	tip party +

The central office terminal equipment consists of three voice-frequency oscillators and three associated keyers. These keyers connect the oscillators in different combinations to the circuit and so vary the voice-frequency tones transmitted over the carrier system. One of these keyers is activated whenever the plus d-c bias voltage is applied to the tip or the minus d-c bias voltage is applied to the ring of the voice-frequency input circuit to the terminal. This keyer is called the "either-or" circuit and it controls the oscillator generating 1,150 cycles. The second keyer is activated if either plus or minus d-c bias voltage is applied to the tip of the input circuit. This keyer is called the "if" circuit and it controls the oscillator generating 1,750 cycles. The third keyer is activated whenever the 20-cycle a-c tone is applied between either tip or ring and ground of the input circuit. This keyer is called the "when" circuit as it controls the oscillator generating 2,500 cycles at a 20-cycle rate. The information of any particular ring is transmitted to the remote terminal by combinations of these three tones. The information to identify which station is to be rung is shown in Table I. The output of these oscillators is amplified by a 1-stage common-emitter transistor amplifier and applied to the input of the carrier modulator as a voice signal.

The remote terminal equipment consists of a 3,000-cycle oscillator as a ringing generator and three signaling tone detectors, each with associated rectifier and relay circuit. The ringing power is provided by the 3,000-cycle oscillator which is a square-wave generator. It is a 2-transistor oscillator with a 2-watt *6A* transistor in the output stage. Its output is rectified by two full-wave rectifiers, one of which produces plus direct voltage and the other minus direct voltage. The 20-cycle a-c power required for ringing is obtained by alternately connecting the plus or minus voltage to the line at a 20-cycle rate.

The signaling-tone detectors are connected to the transmission circuit at the output of the channel expandor at all times when the subscribers are "on-hook." Under this condition the talking path is disconnected to increase the response of the detectors.

The signal tones as received at the remote terminal are amplified by three 1-stage common-emitter transistor amplifiers in parallel, with a tuned circuit in the output of each amplifier to select its

proper tone. This tone is then rectified by a half-wave silicon-diode rectifier and the resulting direct current is applied to the associated mercury relay. The 1,150-cycle signal tone activates the relay and then connects the plus bias voltage to the tip or the minus bias voltage to the ring of the line. When this relay is not operated, minus bias voltage is applied to the tip or plus bias voltage is applied to the ring. The 1,750-cycle signal tone activates the relay that grounds the ring of the line. When this relay is not operated, the tip of the line is grounded. The 2,500-cycle signaling tone activates the relay that alternates at a 20-cycle rate the plus or minus ringing voltage that is applied between ground and the nongrounded side of the line.

Thus, the proper choice of plus or minus bias voltage, the creating of the 20-cycle ringing voltage, and the application of them between the tip or ring and ground is determined by the reception over the carrier circuit of the three in-band signaling tones.

Subscriber Signaling

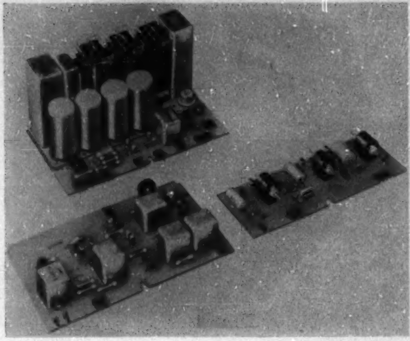
Two types of signaling are transmitted from the remote to the central office terminal. These are supervisory and dialing.

The subscriber in removing the handset establishes battery on the line or an "off-hook condition." This off-hook condition operates relays to activate the transmitting amplifier and to remove a short-circuit on the input of it. The remote terminal carrier is then transmitted to the central office. At the central office terminal the received carrier is amplified by the receiving amplifier, and a part, needed to activate the signaling equipment, is obtained from the output of the receiving amplifier. This output is amplified by a 2-transistor amplifier, then rectified, and the resulting direct current is applied to a relay which establishes a d-c path in the line to the central office. This operation recreates in the central office signaling circuit the line short circuit of the subscriber and brings in the supervisory signaling.

When the subscriber dials, he opens and short-circuits the subscriber line at each dial pulse. The opening of the line operates the relay that short-circuits the transmitting amplifier input but does not disconnect the amplifier power. The relays in the central office follow the pulsing of the received carrier, recreate the dial pulses there, and excite the selector equipment.

Repeater Transmission

The *P1* carrier system uses repeaters whenever the line transmission loss exceeds the maximum the terminals can accommodate. These repeaters use transistors for gain in place of vacuum tubes but otherwise are schematically very much like the repeaters of the type-*C5* carrier system. A block schematic for a repeater is shown in Fig. 9. The two directions of transmission have similar functions, differing only in the frequency band that is amplified and in the options that are used in the gain-regulating cir-



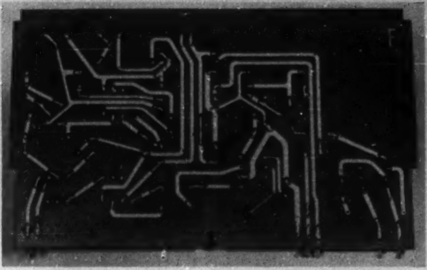


Fig. 14 (left). Typical coded networks using printed wiring board

Fig. 15 (above). Wiring side of typical printed wiring board

cuits. These options adapt it to the conditions of a particular system. Systems containing a single repeater may not require regulation, in some cases, depending on the plant layout.

The regulation in the outward direction from the central office terminal uses the integrated power of the channel carriers to determine the desired repeater gain. The regulation in the inward direction to the central office terminal use, a pilot frequency to control the regulation, as the channel carriers are present only when the channel is in use.

The repeater has identical high-low pass directional filters at each end of the repeater to separate the directions of transmission into the high- and low-frequency groups. When more than one repeater is used along a line, these directional filters have optional phase-correction sections to prevent side-band demodulation bucking. The directional filters are connected to the line through the same line-matching coils and secondary protection circuits used for the terminals. Between the drop sides of each pair of filters there is an input adjusting pad, an equalizer, a regulator, an amplifier, and an output adjusting pad. These output pads permit all levels to be adjusted to within 1 db of the desired transmission level. The input pads are used to build out the line loss for a non-regulated repeater to its maximum value and for a regulated repeater to build out the line loss so as to center the repeater regulator. These pads are in 2-db steps up to 30 db.

The equalizer is designed to a compromise characteristic of the many types of transmission line that are usual in the rural plant. The design covers both groups with one unit so that identical equalizers are used for both the high-group and low-group sides of the repeater.

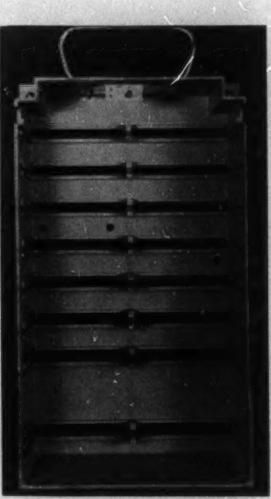

Fig. 16. Prototype model of connector box unequipped showing grid wires

The repeater regulators are backward-acting devices using a shunt-type variolosser in front of the repeater amplifier; they are controlled by the signal at the amplifier output. The regulator control circuit in the outward direction from the central office terminal is not frequency-sensitive and integrates the power of whatever channel carriers are present. This power is then amplified by a transistor amplifier, rectified by a voltage doubler, and applied to the variolosser to provide the loss. The rectifier has an average voltage type of response so that the regulator loss will not respond to the rapid fluctuations of power in the channel side-bands which are 9 db below the carriers. The reference to determine the regulator level is obtained, as for the terminal regulators, from a reverse breakdown silicon diode of about 5 volts.

The regulator control circuit in the inward direction to the central office terminal is frequency-sensitive. It uses a crystal filter at the input of its control circuit so that only the pilot frequency will activate the control circuit. This regulation uses a peak signal rectifier as only the pilot frequency is present. The regulator control amplifiers use transistors in common-emitter circuits, with sufficient feedback to stabilize their gain.

The repeater amplifiers are designed to cover both groups so each repeater contains two identical amplifiers. The amplifier is a 3-transistor amplifier with each stage connected as a common emitter. It uses p-n-p type-*7B* and *6B* transistors in the first and last stages respectively, and an n-p-n type-*4C* transistor in the second stage. Local feedback is required around each transistor to reduce the gain spread and phase variations among units. Over-all feedback is obtained around the three transistors with high-side hybrid coils at input and output. Output pads similar to the input pads are used at the repeater output to permit co-ordination of signal levels among joining systems on a multiple circuit line.

The characteristics of a typical repeater are shown in Figs. 10 through 13. These characteristics are taken from preliminary laboratory design data but are indicative of the final product. The repeater gain frequency characteristic, Fig. 10, is shown plotted with the design objective. There is significant departure only at the cut-apart frequencies. This will be

corrected sufficiently to permit as many as five repeaters to be used in tandem. As this objective is a compromise of the loss among several types of lines that are standard for this system, the departures in system use will vary considerably from these shown.

The repeater amplifier gain frequency characteristic, Fig. 11, shows the nonregenerative peak gain of the 3-stage transistor amplifier of 80 db, and the feedback gain characteristic of 50 db. This provides 20 db or more of feedback over the transmitted band to produce the necessary operating stability with temperature and battery variations and a working value of modulation suppression.

The repeater modulation characteristic, Fig. 12, indicates that the repeater will operate in the system with overload margins very similar to those in the type-*N* system which has proved satisfactory.

The regulation characteristic, Fig. 13, indicates a 15-db range with an input-output stiffness ratio of about 10. This provides an output constant within 1/2 db of line-up value. This characteristic is a design objective that will be closely met. To date, sufficient data are not available to plot a design performance curve.

Power Requirements

One of the unique requirements for this system was that the power consumption be an absolute minimum especially for the remote terminal. The use of transistors has aided greatly in that endeavor. Their use has also eliminated the need for the 130-volt battery required for vacuum tubes. As transistors do not require any warm-up time, the circuitry has been arranged so that, in the remote terminal, the compressor, carrier oscillator, transmitting amplifier, and supervisory relay consume power only when the subscriber is off-hook. These arrangements produce a remote terminal requiring only 0.6 watt of power during the idle period and only slightly more than 2 watts during the off-hook talking period. The majority of this off-hook drain is the transmitter current required by the subset. The ringing period requires about 8 watts additional power but is on less than 1/2 per cent of the time and so represents very little long-time drain.

The similarity of transmission circuitry in the two terminals has also produced a central office terminal with a very low power drain. It is about 2 watts. It is more than the remote terminal because the apparatus at the central office is not turned off during idle periods as the added circuitry is not warranted where ample power is available.

These low power consumptions indicate a real economical system. The measure of how well the low power design objective has been realized is shown in Table II which lists the powers required by several parts of this system and those

Table II. Power Requirements, Watts

of the type-*N* system which function alike, except that one uses transistors and the other vacuum tubes. Further description of the power arrangements is given in reference 1.

Equipment

As mentioned earlier under the broad objectives of the system, the equipment for a rural carrier system must have low cost and provide ease of maintenance, particularly at remote locations. This has been accomplished for the *P1* carrier with plug-in units using printed wiring with miniaturization of components as necessary.

The first step in the equipment design was to break down the terminal and repeater circuits into logical sections and to assign a network code to each section. The terminal for example has the following breakdown of networks:

1. Line connector.
2. Oscillator-modulator and transmitting filter.
3. Receiving filter (half board).
4. Transmitting amplifier (half board).
5. Receiver amplifier and demodulator.
6. Compressor.
7. Expandor.
8. Signaling-tone amplifier and detector (remote).
9. Signaling-tone oscillator (central office).
10. Signaling and voice-frequency circuit.

With the view towards mechanized assembly, printed wiring circuitry has been employed. This also simplifies assembly, testing, and inspection and assures a more uniform product. With the exception of a few heavy components such as relays and large transformers, all apparatus components are mounted directly on printed wiring boards and held in place by their own leads inserted into holes in the printed wiring boards and soldered directly to the printed wiring "lands." A land is the area on the leads where connections are made.

Each coded network consists of its apparatus components mounted on a printed wiring board. The boards are equipped with a unique design of terminal connector, described and illustrated in this article, which permits them to be easily plugged into a wire grid assembly.

The transmitter amplifier and receiver-amplifier demodulator are frequency-conscious and, therefore, have a code for each assigned frequency, i.e., 12, 24, 36, 48, 60, 72, 84, and 96 kc. Thus a plug-in board of the desired frequency can be readily inserted or replaced as required by job conditions.

Fig. 14 shows a group of typical networks as viewed from the apparatus side. The major boards measure 8 by 5 inches and are made of 1/16 phenol fibre with 2-ounce laminated copper on one side only. For small networks half boards are used, two being clamped together before insertion into the connector. Fig. 15 shows the printed wiring side of a typical network with the code number, name, and mounting position letter (*F*) etched with the circuitry, and tinned prior to soldering the components in place. With the view towards automation, the pigtail components and straps on the boards are laid out in definite patterns on predetermined modules.

The networks which go to make up a terminal or a repeater for one channel are mounted in an inner box known as a connector which will accommodate nine networks. The connector is a cast phenolic box with grooves for retaining the

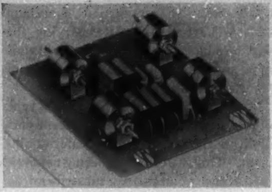

Fig. 24. Receiving channel filter

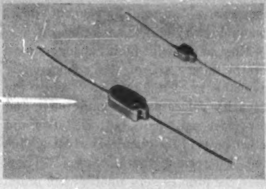

Fig. 25. Tantalum capacitor

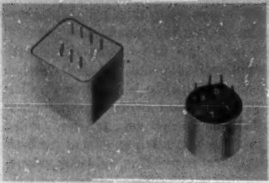

Fig. 26. Carrier-frequency and voice-frequency transformers

boards. The groove positions are identified by letters starting with *A* at the top of the connector. Fig. 16 shows a prototype model of the connector. The rear of the connector consists of a grid of 36 accurately spaced 22-gauge copperweld wires which are the means of making connections between networks. A connector box measures 15 by $8^{1}/_{2}$ by $5^{3}/_{4}$ inches. Connections to the grid are accomplished by the use of terminal connectors fastened to the boards. Each terminal connector consists of a pair of bifurcated cantilever springs made of phosphor bronze. Fig. 17 shows a close-up view of the terminal connectors. These terminals are used at the front of the networks as test connectors and provide a means for hooking on a portable test set. A protective coating on the grid wires and terminals affords better wearing quality.

The chief advantage of the foregoing design is the ease with which an entire terminal or repeater can be carried to an installation or a maintenance depot where it can be quickly installed or replaced in its entirety, or by networks, as required. Also, as brought out earlier, the frequency assignments for a line can be quickly changed by plugging in networks of desired frequencies into the terminals, and the expanded or changed traffic conditions are ready to be served.

A complete terminal, except for the line network, is illustrated by Fig. 18. The bottom position in this terminal contains the network for the signaling circuit which employs wired-in conventional relays as well as printed wiring circuitry. The top position, shown vacant in this figure, is where the line network mounts. The line network connects the terminal to the line and power supply through a local cable connected to screw terminals on the network. The outer end connects to a gasketed terminal block at the top of an outer housing, known as an apparatus case, at remote locations. Carbon block protectors are built into the terminal block for the line leads. A secondary protection circuit, referred to earlier, consisting of a series resistor and a pair of diodes connected back-to-back in shunt across the line is provided at remote locations. The latter is located on the line network. Also on these networks are mounted input and output pads which can vary the levels. These pads are fastened to screw terminals and are readily interchangeable. They are available in 2-db steps up to 30 db.

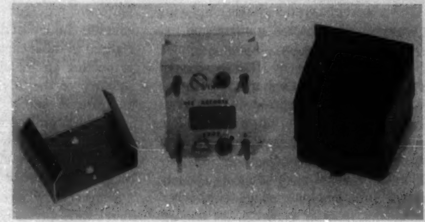

Fig. 27. Carrier blocking network

Fig. 19 shows a pole-mounted terminal with its associated power supply mounted above it, both being mounted in apparatus cases of the same size. These cases have an over-all measurement of $12^{1}/_{2}$ by $23^{3}/_{4}$ by $10^{5}/_{8}$ inches.

The apparatus case is made of die-cast aluminum and is built of two similar halves. A round O-ring neoprene gasket is used to seal the two halves to keep out moisture. A 10-ounce bag of silica-gel is placed in the bottom of each case to keep the moisture content of the trapped air to a minimum. The two halves are secured together by 16 screws to assure even pressure on the gasket. The case is painted white to reflect the heat from the sun. Sun shields may be used where extreme temperatures prevail as a further means of keeping the temperature inside the case to a minimum.

The terminals in central office, are arranged to mount in pairs on a 19 inch relay rack and, with the associated terminal strips and carrier blocking networks (when required), they occupy 21 inches of vertical mounting space. They may also be wall-mounted.

The line network for both central office and remote locations can be removed from the connector box and stored in a shelf located directly under the connector without disconnecting the local cable. This permits the connector and its remaining networks to be removed as a unit. The shelf position can be seen in Fig. 19.

Repeaters mount the same as terminals in remote or central office locations. At a remote location the terminal or repeater is mounted on the pole to be accessible from the ground for convenient maintenance. Conventional saddles are used to mount the apparatus cases to the pole, as shown in Fig. 20. This figure also illustrates the use of flexible conduit known as "greenfield" or "flexsteel" to protect physically the external wiring.

With the arrangement described there is no need for any soldering operations at remote locations since the plug-in units can be readily replaced because of failure of components, or an entire terminal or repeater can be carried in its connector case and be substituted as a complete unit by simply storing the line network and loosening two screws at the top of the connector case. Testing of the equipment is accomplished in the field by the use of a specially designed unit, as shown in Fig. 21.

Components

Development of the passive components of the *P1* carrier system including the various filters and other networks were influenced by three major considerations. Again, the manufacturing cost had to be as low as possible, though the traditional standards of Bell System service life had to be maintained. The components had to lend themselves to maximum utilization of the printed wiring techniques to be used as the basic equipment method. And lastly, advantage wherever possible was to be taken of the fact that transistors are low-power devices.

Componentwise, filters are the most important single assembly determining the first cost of a carrier system employing frequency division multiplexing and frequency separation for obtaining equivalent 4-wire operation on the line. Experience has shown that one-quarter or more of the first cost is chargeable to the various filters. Much attention was therefore paid to this problem even in the system planning stage. The decision to employ double-side-band modulation was largely based on the knowledge that, when frequency space is available, the double-side-band channel filters are generally less expensive.

With this decision made, every effort was directed toward the achievement of channel filter designs of maximum efficiency in element utilization. Advantage was taken of the more leisurely rising characteristics of double-side-band filters. Inexpensive wide-limit capacitors are employed, and the desired performance is achieved through the use of an adjustable ferrite inductor expressly developed for the *P1* carrier system. The filters are readily adjusted in the manufacturing process with the use of visual display testing circuits.

The inductor which makes this possible is shown in Fig. 22. It is designed for printed wiring use and provides a wide range of inductance change while maintaining excellent Q performance in the carrier and voice range. This is accomplished in a single basic design by so selecting the winding for particular nominal inductances that the air-gap adjustment remains at or near its most efficient setting. Inductors of this type are used not only in all the channel, demodulator, and signaling filters in the terminal and directional filters at the repeater but also in the channel oscillators and other parts of the circuitry where an inexpensive, adjustable element offers manufacturing or field advantages.

Most of the wide-limit capacitors used in the filters are of the commercially available molded-mica type. Where the capacity values would require large and expensive mica units both in filters and other parts of the circuit, newly available foil-Mylar capacitors are used. These take the form of very small pigtail units, as shown in Fig. 23.

The capacitors have low working voltages in these miniature sizes and can be employed because of the low-voltage protection provided for the transistorized circuits. Both cost and space savings are realized in these capacitors since no cans or potting are required because of the stability of the Mylar dielectric under moisture exposure.

A typical printed wiring assembly of a receiving channel filter is shown in Fig. 24. This unit employs all three of the basic components described in the foregoing.

Another new type of capacitor has found wide-spread use in the *P1* carrier system. This is a solid tantalum electrolytic capacitor used in place of the usual paste or liquid electrolytic capacitor. The solid electrolyte is manganese dioxide deposited upon the capacitor surfaces. The anode is made from tantalum metal and upon its surfaces is deposited the tantalum oxide which forms the dielectric. The cathode is an enveloping metal completing the capacitor structure. The new design of capacitor provides up to 100 microfarads in a very small volume. It is expected to be less expensive than other electrolytic capacitors while at the same time providing a rugged structure, fairly inert electrochemically, with better stability in operation and storage. Fig. 25 shows typical solid tantalum units. Transformer needs in the *P1* carrier system are provided for with two miniature structures which were made possible by the use of low-power transistor circuits.

The carrier-frequency units employ a manganese zinc ferrite core, a spool winding, and wire terminals which permit assembly on printed wiring boards. They are potted with an asphalt compound in a cylindrical aluminum can.

The voice-frequency transformers are wound on laminated core structures of either *45* permalloy or molybdenum permalloy. The units are potted in an epoxy resin in rectangular aluminum cans. The terminal plate carrying the wire terminals for mounting is a cast unit of a styrene polyester. Both types of transformer are shown in Fig. 26.

Also deserving mention is a special type of line network which does not form part of either the terminal or repeater equipment. This is a carrier-blocking network used at each point where a subscriber drop is made from a carrier line. By presenting a high impedance to carrier frequencies, the network prevents absorption of carrier power in the drops. It also prevents any harmonics produced at the subset from interfering in the carrier circuit. Several electrical varieties are available to provide for the various lengths of subscriber drop.

The physical arrangement is shown in Fig. 27. The networks are cast in a styrene polyester. High-voltage protection is self-contained and sturdy terminals are provided for bridle-wire connection. By means of side slots in the casting, the network may be mounted on a wedge-shaped holder which is fastened to the pole. A flexible rubber cover is snapped over the face of the network to protect against deleterious weather effects.

Conclusion

The design objectives for this system required a new approach to almost every phase of the development. The use of transistors introduced sweeping changes in the detailed circuitry and created the demand for many new component parts. The use of printed wiring introduced a new necessity for close co-operation between design and manufacturing objectives, and the desire for low cost was an important factor. The necessity for field flexibility and ease of maintenance required extensive broadening of the training and handling concepts. All of these factors have been blended into this design, and its introduction into the telephone plant will give another indication of the use of carrier systems to provide good quality of communication service at low cost.

Application of the Type-P1 Carrier System to Rural Telephone Lines

J. D. HOWARD, JR.
MEMBER AIEE

THE rural service situation is one of the most pressing and difficult problems to solve in the telephone industry. The use of fixed outside plant such as cable, open wire, or *B* rural wire (6-pair distribution wire or cable) proves expensive in many instances for providing each customer in the rural area with the grade of service he desires when he wants it. This is particularly true for rural areas because of the difficulty of accurately forecasting rural service demands.

The advances in the electronic field in the past decade have resulted in improved carrier equipment at substantially reduced cost so that shorter and shorter telephone circuits have been provided economically by carrier. The use of carrier systems in the trunk and toll fields is already paying off in economy and flexibility by providing circuits with movable equipment and a minimum of fixed outside plant. Therefore, if sufficiently low-cost carrier equipment can be obtained and used as a general method for supplying rural circuits, it should provide similar economy and flexibility since the capacity of any line or cable could be expanded and contracted at will as the demands occur. This concept has been the basis for the development of rural carrier systems.

The transistor, with its associated low-power consumption which allows the use of low-voltage and subminiature size capacitors, resistors, and inductors that can be interconnected on printed wiring boards and are adaptable to automatic factory assembly, point toward carrier equipment of sufficiently low cost to be attractive for providing rural telephone circuits. Therefore, transistors and printed wiring assemblies have been incorporated in the *P1* carrier system design.

The first requirement for the *P1* carrier system as for any rural carrier system is low cost but, unless the system can be applied to existing base plant by means of simplified engineering of carrier line layouts and installation and can be easily maintained, and other papers[1-2] show how the *P1* carrier system has been designed to enable a simplified approach to carrier line layout, installation, and maintenance to meet the over-all requirements for an economical rural subscriber carrier system.

Application of P1 Carrier

The *P1* carrier system is to be applied to normal exchange base plant facilities engineered in accordance with the resistance design methods as covered in a paper by Bogan and Young.[3] These facilities consist of mixed gauges of high-capacitance cable extended at their outer extremities by *109* steel, *104* copper, or copper-steel wire. A typical rural plant and the problems involved in carrier application on this type of facilities were described in a paper by Hochgraf and Watling.[4] A review of both of these papers will be of considerable value in understanding some of the basic concepts discussed in the following.

To engineer the carrier line design or carrier layout, the engineer must be familiar with the basic capabilities of the carrier system, but he need not have a complete knowledge of carrier-system operation. He is primarily concerned with the basic "building blocks" and the limitations that must be considered in applying the system to the physical line. The basic building blocks are as follows:

1. Central office terminals.
2. Remote terminals.
3. Repeaters.
4. A-c or d-c remote terminal and repeater power supplies.
5. Low-pass filters.
6. High-pass filters.
7. Carrier line termination.

Fig. 1 shows in block schematic form a carrier application of all of the various components listed in the foregoing. In addition to these, an autotransformer or junction line filter may be required at the junction of the open wire and cable. The autotransformer is required to eliminate reflection losses and to reduce crosstalk at carrier frequencies caused by impedance mismatch of the cable and open wire. The junction line filter is required to allow the carrier and the physical voice-frequency (VF) circuit to be on different pairs in the cable section, where the physical circuit is so long that load coils are required for VF and nonloaded cable pairs are required for the carrier, and the same open-wire circuit is used for both voice and carrier beyond the cable open-wire junction.

Fig. 1 gives an example of two types of subscriber distribution beyond the remote terminals referred to as wire distribution and filter distribution. Wire distribution is indicated by the VF extensions of channels 1 and 4, and filter distribution is shown for channels 2 and 3 and for the physical VF circuit.

The application of the *P1* carrier consists of determining the carrier line layout necessary to meet the over-all requirements for a suitable carrier transmission path on the available physical facilities. To do this adequately, the engineer must be given certain ground rules based on the characteristics of the carrier system.

The *P1* carrier system operates in the frequency range of 8 to 100 kc with three frequency arrangements, as shown in Fig. 2. The stackable frequency arrangement utilizes adjacent frequencies to provide for opposite directions of transmission and is used for nonrepeatered operation. The design of the carrier system is such that the bare line loss at the top frequency of each individual channel can be 30 decibels (db) from the central office terminal to the remote terminal, as shown in Fig. 3(A). The VF extension beyond the remote terminal can be 390 ohms (5 miles of *109* steel wire). The 390 ohms are controlled by the talking battery supply requirements of the subsets with the battery being supplied from the remote terminal power supply. The *P1* carrier system has been designed to operate with the *500*-type telephone set as this set insures better over-all performance because of its improved dialing, ringing, and transmission aspects. The over-all transmission of a carrier channel and its VF extension with the use of the *500*-type telephone set will be as good or better than that obtained on long rural lines with physical plant laid out by the afore-mentioned resistance design method.[3]

Paper 56-241, recommended by the AIEE Committee on Wire Communications Systems and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30-February 3, 1956. Manuscript submitted October 20, 1955; made available for printing December 13, 1955.

J. D. HOWARD, JR., is with American Telephone and Telegraph Company, New York, N. Y.

Fig. 1. Typical system application

The normal and staggered grouped frequency arrangement are for repeatered operation and the system design allows 30-db bare line attenuation at the top frequency (96 kc) either between the central office terminal and the first repeater, or between repeaters and between the last repeater and the remote terminal 30 db at the particular frequency involved with the individual channel. The repeatered system can use a maximum of four repeaters for a total line loss of 150 db at 96 kc. The repeatered arrangement is shown in Fig. 3(B). Referring to this figure, it can be seen that, of the four repeaters, a maximum of two are permissible in open wire with the last cable repeater at least 1 mile back in the cable from the cable open-wire junction. These requirements are based on noise and crosstalk objectives.

In addition to bare line loss, there will be approximately 3 db of miscellaneous losses in any normal channel layout including carrier blocking networks, high-pass filter losses, bridging losses of other terminals on the carrier line, cable and open-wire junction autotransformer losses, or cable and open-wire junction line filter losses. Since these losses do not add in phase, it is simpler to use an average loss factor to cover most conditions rather than to make computations to determine a definite loss for each set of conditions that might exist. Thus a total of 33 db including the bare line loss plus miscellaneous loss from terminal to terminal may be expected. The maximum system transmitting line level of each sideband is −8 db (referred to the channel 2-wire input 0 db level point). Carrier is transmitted 12 db above each sideband or +4 decibels referred to 1 millivolt (dbm) at the terminal output to the carrier line (i.e., −8-db system level point). The maximum transmitted carrier energy is +4 dbm at the central office line terminals and +0.5 dbm at the remote terminals on the carrier line, i.e., where the remote terminals are bridged to the line after experiencing about $3^1/_2$-db bridging loss. Therefore, the minimum carrier power in the central office to remote direction will be −29 dbm (+4 dbm −33 dbm = −29 dbm) at the bridging point of the remote terminal. In the remote-to-central-office direction, the minimum power will be −32.5 dbm (0.5 dbm −33 dbm = −32.5 dbm) at the line connection of the central office terminal.

The *P1* terminals provide 15 db of automatic channel regulation and the repeaters provide 10 db of automatic group regulation to counteract variations and loss caused by weather changes. Input and output pads at the terminals and input pads at repeaters are provided where necessary to eliminate the possibility of overloading the equipment by building the line section out to required loss.

In laying out the carrier line design, it is necessary to determine the possible locations for the remote terminals based on accessibility to the subscribers to be served and the availability of commercial power since this type of battery supply will be the most economical. Of course, when a-c power is not available, the primary air-cell batteries can be used. Having determined the ideal location of the terminals from a physical standpoint, the makeup of the physical circuits back to the central office must be determined and computations of the facilities attenuation at carrier frequencies have to be made to determine the location and number of repeaters required, if any, and to check for the necessity of input and output pads at the terminals.

The many variations in the exchange plant facilities such as a mixture of 26-, 24-, 22-, and 19-gauge cable would make a factor-computing method very laborious. This pointed to the need of a simplified method of determining the carrier line losses. This led to the development of length-loss charts so that a carrier line design could be made very similar to the loop cable design with the use of the resistance design methods as

mentioned in the foregoing.[3] Fig. 4 shows the 96-kc length-loss chart based on maximum facility loss (+140 degrees Fahrenheit loss factors for cable and wet or ice conditions for wire) which is used to lay out repeater spacings and channel-4 over-all circuit design. Figs. 5 and 6 are examples of the maximum and minimum loss charts for other carrier frequencies utilized. These charts are used for terminal-to-terminal section layouts of all but channel 4 and repeatered systems using the normal or staggered frequency arrangements.

In addition to information on repeater spacings and terminal spacings based on facility loss at carrier frequency, the engineer must know how many channels of carrier can be applied to each circuit of open wire, cable, or *B* rural wire. In regard to cable and *B* rural wire, crosstalk tests have indicated that four channels of either the stackable or normal grouped frequency arrangement can be used on each pair, or the three channels of the staggered grouped frequency arrangement can be used on each pair. However, in the case of open wire, the frequency arrangement and number of channels are very dependent upon the type of transposition system used. The most commonly used transposition system in rural lines of the Bell System is designated the *R1*. Table I gives the carrier assignments for the various frequency arrangements on a 1- and 2-crossarm route utilizing the *R1* transposition method.

Table I. Number of Carrier Channels that Can Be Assigned to the Open-Wire Circuits in Accordance with the P1-Carrier Frequency Arrangements

Pins	Stackable	Grouped
1 and 2	4	4*N**
3 and 4	1	3*S*†
5 and 6	0	0
7 and 8	4	4*N*
9 and 10	2	3*S*
Total for one crossarm	11	14
11 and 12	1	0
13 and 14	2	0
15 and 16	0	0
17 and 18	4	4*N*
19 and 20	4	0
Total for two crossarms	22	18

* *N*—normal frequency arrangement.

† *S*—staggered frequency arrangement; see Fig. 2.

The stackable and grouped frequency arrangements do not co-ordinate and cannot be used on the same line. The group normal and group staggered arrangements do co-ordinate and can be used on the same line. Referring to Table I a 1-arm route using the stackable frequency arrangement will provide for a maximum of 11 carrier channels, and a 2-arm route can have a total of 22 channels.

In the case of the group systems, 8 channels of the normal frequency arrangement can be used on one arm or 12 on two arms and, with a combination of normal and staggered, a total of 14 channels can be used on one arm and 18 channels on two arms. It will be noted that the group arrangement provides 4 channels less on a 2-crossarm basis than the stackable arrangement which is primarily an economic consideration in that the grouped arrangement is used for repeatered operation with repeaters handling a complete system of three or four channels; this makes repeaters rather expensive for a single- or double-channel circuit assignment such as exist for the stackable frequency arrangement on pins 3 and 4, 9 and 10, 11 and 12, and 13 and 14.

Length-Loss Carrier Line Design

To show how a carrier line design is arrived at by use of length-loss charts, the following example is presented to give the step-by-step procedures required. Fig. 7 shows in schematic form a typical rural layout indicating the gauge and type of existing facilities and the existing 1-, 5-, and 10-year line fills that will be encountered at major points along the route. Schematics of this type are the first step in engineering additional telephone facilities after a commercial forecast has been made to determine the potential demand for telephone service in the area to be served.

Referring to Fig. 7, the present facilities beyond the existing cable consist of 5 pairs of *109* steel wire, and the line fill requirements indicate that 7 additional pairs are needed initially with a total of 15 additional pairs in 10 years. Therefore, the problem is to determine the possibilities of carrier in serving these requirements versus other types of facilities such as cable, additional open wire,

or *B* rural wire. The use of carrier versus cable or open wire to care for the facility requirements of a particular job must, of course, include a cost study to determine how much carrier and how much physical plant should be added to provide the most economical arrangement. However, after experience is gained in a given area with the use of carrier, these studies will be simplified to the extent that a prove-in length of carrier versus physical plant can be established. Thus, the prove-in length can be used to determine the economical solution very easily. Therefore, in the following it is assumed that the proper economic solution has been determined and the use of carrier as applied provides the economical carrier line design.

Referring to Fig. 7, between 20 and 40 kilofeet (kf) only four circuits will be used in the 10-year period, and between 40 and 60 kf only three circuits are used in the 10-year period. Therefore, the existing VF facilities, with the addition of 20 kf of 6-pair *B* rural wire between 20 and 40 kf would provide all the necessary service for the 10-year period out to 60 kf. The increase of nine circuits beyond 60 kf of which six extend to 90 kf and three beyond 90 kf can be served by carrier. Therefore, the first step is to determine the number and location of repeaters required and the proper channel allocations to the existing facilities to provide a tentative carrier layout of the initial, 5-year, and 10-year additions. To do this, a plot of the appropriate length of each type of facility is made on the 96-kc length-loss chart, as shown in Fig. 8. It can be seen from this chart that the remote terminal of channel 4 could be placed at 97 kf with a maximum of three repeaters per carrier system. Therefore, there will be no problem in providing these circuits via carrier.

The next step is to determine the best method of carrier frequency arrangements so that the minimum number of carrier systems and, thus, the minimum number of repeaters will be required. An expanded sketch of Fig. 7, as shown in Fig. 9, can now be made to indicate the number of channels needed for the three periods of growth on which the remote terminals are designated in accordance with service requirements. This sketch indicates that 6 carrier channels will be needed initially, 9 carrier channels in 5 years, and 11 carrier channels at the end of the 10-year period. Therefore, two normal group frequency arrangements and one staggered frequency arrangement will fill the 10-year requirements. Referring to Table I for open-wire carrier system assignments, it can be seen that four normal frequency channels can be applied to pins 1 and 2, and 7 and 8, and the three staggered frequency channels can be assigned to pins 3 and 4 or 9 and 10. Therefore, the third step would be to make a pole-head schematic to show the existing pin positions of the wire presently in plant from 60 kf on out, from which could be determined the best carrier assignment, as shown in Fig. 10(A) (B), and (C). In Fig. 10(A), the initial carrier assignments are made on pins 3 and 4, and 7 and 8 with a complete system of four channels using the normal frequency arrangement placed on pins 7 and 8 and two channels of the staggered frequency arrangement operating on pins 3 and 4 in the multicircuit portion of the loop, and the actual terminals working from a bracket circuit extending beyond 90 kf.

Once the terminals have been located, the carrier design is made final by determining the values of input and output pads to keep the circuit net loss within the automatic regulation range of the equipment. As an example, the pad values for channel 1*S* are determined by plotting the facility loss on the 66-kc maximum loss chart and the 18-kc minimum loss chart. The origin of the chart represents the last repeater location or 63 kf in the example for the maximum loss chart and the terminal location for the minimum loss chart, since the higher frequencies are transmitted from the central office to the remote terminal and the lower frequencies conversely.

Vol. 7
Pt. 1
1956

(Continued from page 209)

Figs. 11(A) and (B) show the plot on the maximum and minimum loss charts from which the value of the input pad at the remote terminal and the output pad at the remote terminal can be read directly as follows: the maximum allowable loss between the repeater and the remote terminal is 30 db at 66 kc and the facility plot indicates that the loss is only 24 db. Therefore, the input pad should be the difference in these two values, or 6 db. Fig. 11(B) shows the plot from the remote terminal back to the last repeaters for the minimum loss of 18 kc which is 8.5 db. The maximum repeater gain at this frequency, shown by the line on the chart, is 19.5 db. Therefore, the output pad for the remote terminal is the difference between the repeater gain and the facility loss, or 11 db.

The next step is to determine the input pad values for the repeaters in the remote-terminal-to-central-office direction. These pads are required in this direction only, since the repeaters are laid out on the basis of maximum frequency and the gain slope of the repeater is such that pads would not be required in the 60- to 96-kc band with the repeaters laid out on the basis of a 96-kc loss. However, in the 12- to 48-kc band, the variation in repeater gain is sufficient to result in the possibility of repeater overload based on 96-kc spacing. Therefore, the maximum loss at midband frequency, or 30 kc for the low-group direction, is plotted for each repeater section in the remote-terminal-to-central-office direction, and an input pad is placed at each repeater which is equal to the difference between the maximum facility loss and repeater gain at 30 kc. This is illustrated in Figs. 12(A) and (B). In a similar manner, each of the remote terminal input and output pads can be determined, thus giving a complete carrier line transmission design.

The next step in completing the carrier line design is to determine the proper filter network to be placed at the junction of the carrier line and side leads, or drops, serving VF derived circuits, which are served from the base carrier facility between remote carrier terminals. These filters are required to reduce the reflection losses at carrier frequencies of the side leads and to prohibit carrier from being transmitted into the subscriber subsets, since certain types of subscriber subsets, such as the *500* set which is the recommended set to be used with *P1* carrier, are susceptible to carrier frequencies from a noise standpoint because of the demodulation qualities of certain of the subset components. These low-pass filters or carrier-blocking networks are designed to match given ranges of capacitance that will be encountered from drop wire or open-wire side leads. Since this capacitance varies considerably with various lengths of facility, and equivalent capacitance-length chart for the various types of facility is provided from which the total capacitance can be determined and the proper network chosen. See Fig. 13.

This covers the details of a carrier line design with the exception of the placement of high-pass filters used to sectionalize portions of the line for VF distribution where filter distribution is used and for placing the carrier line termination at the bridging point of the last carrier terminal on the line.

Installation and Maintenance

The *P1* carrier system utilizes plug-in equipment throughout primarily as an aid in making installation and maintenance procedures as simple as possible. The plug-in feature allows individual printed wiring boards or an entire carrier terminal to be easily replaced by spare equipment without requiring extensive maintenance procedures. To simplify this process further, a test set has been designed which will provide all of the necessary carrier and VF and a means for measuring them. The installation consists of lining up the over-all carrier circuit for specified values to be read at special test points built into the equipment, and of adjusting certain potentiometers or inserting given values of pads to meet the over-all requirements. The installation and line-up procedure is set up on the basis of using the test set to make a series of measurements in a specified order, with signals being supplied at the central office and received at the remote terminal or vice versa and of adjusting potentiometers in the equipment until the specified meter readings are obtained. The original line-up results will be recorded for future reference on maintenance calls. Maintenance will be handled on a complete terminal replacement basis and will consist of making a series of checks with the test set to determine whether the terminal is functioning satisfactorily. If it is not, and if it cannot be adjusted to restore satisfactory operation, a replacement terminal will be used to restore service. All repairs and isolation of trouble within the terminal unit will be handled at a centralized testing point so that a minimum of personnel with electronic experience will be required. However, the test set itself has been designed to handle all tests for a *P1* carrier system and, when used by experienced personnel, will enable the complete testing of the *P1* carrier equipment. Therefore, one test set can be used for installation, maintenance, and trouble isolation.

The remote terminals are hermetically sealed and test points have been brought out to the terminal strip outside of the remote terminal housing so that the housings will not have to be opened unless tests performed at these points indicate that the terminal is in trouble.

Conclusion

The use of carrier equipment in large quantities to provide subscriber telephone service places requirements on equipment and personnel that are far more difficult than exist with equipment located in central offices or fixed places. Therefore, every effort has to be made to make the maintenance of this equipment as simple as possible. Also, the flexibility required to provide subscriber service makes it necessary to use a wide variety of facilities in the exchange plant. Carrier is merely one of the many that must be considered by the engineer. Thus, for the proper use of carrier, it is necessary to have some simplified methods of application that allow a fast and accurate way of laying out a carrier line design. The use of length-loss charts provide such a method and the use of plug-in equipment with designated test points and a test set with detailed instructions allow for an over-all ease of engineering and application that is necessary for the present technical ability and work load of the operating forces of the telephone company.

Discussion follows

Discussion

J. M. Moss and **D. I. Cone** (The Pacific Telephone and Telegraph Company, San Francisco, Calif.): The application methods described by the author are a far cry from those used in toll line carrier design. Great simplification is possible because of the basic design of the system and the use to which it will be put. Even so, it will mean a great extension of the efforts of the engineer normally engaged in the design of facilities for rural service, beyond his previous customs. Operation and maintenance will likewise change.

Thus it appears that a considerable program of instruction will be required to acquaint these people with the layout procedures, including a sufficient appreciation of the characteristics of carrier transmission to enable them to recognize the need for control of reflections by impedance-matching, line terminations, and filter placement. This same problem faced the central office people when electronic gear first appeared on toll circuits. Questions that seemed immensely complex at first are now solved in routine fashion, and there is every reason to believe that the same result will be achieved with the local plant.

Telephone engineers throughout the country will surely welcome the advent of the *P1* carrier as a powerful aid in expanding rural telephone service. In the problem of determining the economical means of service, devices such as the chart in Fig. 8, serve to make possible quick analysis of the conductor and repeater requirements covering the numerous gauges of cable and open-wire types. Thanks to the work of the research and development groups, standards are set up to make possible a sort of "mass production" application. The burden of determining the standards of design has been recognized and resolved in lengthy interchange of information and ideas between operating people in the field and the group of designers whose conclusions are embodied in this paper and its companions.

Having arrived at this standard, the next step is its application in the field and the inevitable experiment to determine what variations can be profitably made. Those who have experienced the development in application of earlier carrier systems will recognize the possibilities. There is a genuine engineering challenge both to find variations of application that are useful and to understand the fundamental limitations of each such carrier system.

J. M. Flanigan (U. S. Department of Agriculture, Washington, D. C.): The paper gives an excellent presentation of the manner in which the type-*P1* carrier system can be applied to rural subscriber loops. The method of using loss charts for determining repeater and terminal spacing is particularly interesting. In the application of subscriber carrier systems of various types for rural telephone use, however, we have found that numerous situations occur where it is necessary to utilize the same central office entrance cables and portions of the open-wire routes that are used for existing or proposed trunk carrier systems. For these applications the problem of providing maximum co-ordination between various types of carrier systems becomes more difficult, and consideration must be given to the operating frequencies, levels, crosstalk loss achieved between the various wire facilities upon which carrier channels are operated, and the susceptibility of various types of carrier equipment to interfering effects. To achieve maximum economies from the use of subscriber carrier systems in many application situations, co-ordination between carrier systems must definitely be considered initially in the layout of the carrier routes.

There are no illustrations which show the central office carrier terminals mounted at locations external to the central office, such as at cable open-wire junctions. In this type of arrangement more cable pairs are required for the transmission of voice frequencies; there is a maximum distance between the central office and an externally mounted central office carrier terminal over which the desired ringing information can be properly transmitted; and carrier channel testing cannot conveniently begin at the central office. Despite these apparent disadvantages, application situations might arise whereby the placement of a carrier terminal at an external location not exceeding the maximum distance mentioned may reduce the over-all cost of providing service by subscriber carrier techniques by reducing the number of carrier repeaters required in the over-all system arrangement. Although testing of a carrier channel cannot begin in a central office with this arrangement the over-all testing time might still be reduced if fewer repeaters are required.

The paper gives considerable detail as to how to calculate losses for both open-wire and cable facilities at carrier frequencies. Little detail is given, however, as to how the effective transmission objective is altered for the subscriber loop, portions of which are also utilized for carrier transmission, by the insertion of low-pass filters at various locations along this loop. These filters provide an insertion loss at voice frequencies since at least two of them are inserted in the loop on a call between a voice frequency subscriber and the central office. In addition, the remaining low-pass filters would be bridged on the loop in an unterminated condition during a call and would probably cause additional transmission losses at voice frequencies.

Since commercial power for the low-drain chargeable battery type of power supply will be the most economical for powering each remote carrier channel terminal, a minimum power bill will probably have to be paid by the telephone company for each separate remote terminal location despite the very low current drain of the transistorized equipment. If remote terminal locations were combined by the economical utilization of various arrangements of filter distribution, the costs for minimum power bills would be minimized. In addition, a minimum number of remote carrier terminal locations would reduce the time required for periodically testing and maintaining this equipment. If a minimum number of remote terminal locations were economical, an a-c powered low-drain chargeable battery type of power supply with sufficient capacity for powering more than one remote terminal could possibly be more advantageous from an equipment cost standpoint as compared with a separate power supply for each channel terminal, as now provided.

J. D. Howard, Jr.: The discussions are interesting and important. I agree with Mr. Moss and Mr. Cone in regard to the necessity of more extensive training programs for acquainting the Bell System plant engineers and operating people in the concepts of carrier. Also, the possibilities of further techniques in carrier application should certainly stimulate the engineer's thinking and challenge his imagination and intellectual curiosity.

Mr. Flanigan has pointed out several of the engineering aspects of carrier application that need clarification. For example, the possible co-ordination of *P1* carrier and other types of carrier systems. It will certainly be necessary to consider alternate frequency assignments, crosstalk computations, and level differences to determine the optimum carrier application. These techniques are not new in the telephone industry and, rather than attempting to provide training to all of the plant engineers, the company will of necessity have the techniques performed by specialists in this type of work.

As to remote location of the central office terminal of *P1* carrier it should be pointed out that this was not considered in the original equipment design as a requirement because of the decision to provide a carrier system operable over both cable and open wire with repeaters to counteract the high loss of cable plant at carrier frequencies. However, if this becomes a necessity, further refinement of the system might possibly be made, but it must be remembered that this means an additional option and a greater cost that might well outweigh the advantage, since low cost of *P* carrier is of paramount importance. The placement of the central office terminal at a remote location may also require the use of VF repeaters on all of the carrier circuits at the central office to make up for the VF loss of the entrance cable to ensure the proper grade of transmission.

The effective loss of a carrier channel and its VF extension depends on the following factors:

1. Effective transmission of the VF extension.
2. Circuit net loss of the carrier channel and possible variations in this loss.
3. Side-tone impairment due to the use of carrier in the loop.
4. Impairments due to the use of *482*-type networks (low- and high-pass filters).

It is estimated that the total impairment of these filters will be in the order of ±3 db that would be added to the over-all effective loss of a VF rural loop with the exact value depending upon the possible combination of factors involved in a particular situation.

Mr. Flanigan's idea on conserving commercial power taps by combined locations of terminals is very well taken, and the Bell Telephone Laboratories are presently considering the possibility of providing a power unit for more than one terminal. A single battery supply for more than one terminal presents a problem of battery supply filtering to eliminate the possibility of crosstalk between channels, and it may prove to be uneconomical, especially considering that a multiunit power supply may well be a low-demand item, thus further increasing production costs.

Co-ordinated Protection for Open-Wire Joint Use—Present Trends

W. R. BULLARD
FELLOW AIEE

H. E. WEPPLER
MEMBER AIEE

THE EXTENT of use and benefits obtained by the joint use of pole lines to carry power and communications circuits are well known. A number of worthy papers have been presented before the Institute to describe various aspects of joint use and to report on progress in this field.

The power companies and communication companies have long worked in close co-operation to develop techniques which would make possible even more extensive realization of the utility and economy of joint use while still safeguarding the public, the employees, and the essential public services rendered.

As the power and communication systems are extended and adapted to serve best the public's needs, new problems in joint use constantly arise. The extension of joint use from a predominately urban field of application to widespread use in rural areas was an important step which has previously been reported.[1] Similarly, considerations involved in joint installations with power lines of increased operating voltages have been presented.[2,3]

This paper reviews some of the problems encountered in the past few years. Two other papers[4,5] describe field tests which are leading the way to solutions of current problems.

Objectives for Protection

The probability of contact between power lines and telephone lines varies, of course, with the types of plant involved. For example, with power conductors in cable the chance of a failure resulting in a contact with the telephone conductors is remote. However, for obvious economic reasons large portions of the power and telephone plant must utilize aerial wire construction. In joint-use construction of this type, the possibility of contact assumes greater importance. The prime factors in holding to a minimum the occurrence of contacts between the power and telephone conductors are the development and consistent use of safe structural standards. The practices in use have been developed co-operatively over the many years of joint-use construction and are frequently reviewed in the light of current needs.

In the infrequent case where contact does occur the objectives are to minimize the foreign potential developed on the telephone plant and to remove the power voltage from the telephone plant as quickly as possible.

The voltage impressed on the telephone plant during contact is determined by the power circuit voltage and the impedance of the telephone plant between the point of contact and ground as compared with the total impedance of the fault circuit. In the telephone plant it is thus essential to provide for low impedances to ground during faults in order to hold down the foreign potentials.

The length of time the telephone plant is energized is determined in most cases by the time–current characteristics of the interrupting devices in the power circuit and by the magnitude of the fault current. There are, of course, a fraction of the cases in which the contact is only momentary due to the physical nature of the contact itself, and there may be some in which the contact is interrupted by the burning away of the telephone conductors or power conductors at the point of contact. However, electrical protection on joint-use lines is primarily a matter of co-ordinating the ratings of power circuit interrupting devices, power system impedance, telephone system impedance, and telephone system protective devices.

Effect of Growth in Power Loads

With the increasing power loads of recent years, the power companies in a number of cases have found it necessary to increase line voltages to increase the capacity of their lines. At first the joint use of pole lines with power voltages over 5 kv was looked upon as something quite special, but subsequent study and experience have established that properly co-ordinated joint use need not be limited to any arbitrary voltage.[3] In fact, the use of higher power voltages has in many cases facilitated the rapid de-energization of the power line since the ratio of fault current to load current is larger with the higher line voltage.

Still more recently, however, it has become necessary to go to progressively higher currents in some heavy-duty distribution systems. In such instances the impedance of the power circuit is correspondingly lower because of the heavier lines and equipment required to carry the greater load, and because of the influence on design of voltage-drop considerations in normal operation. To minimize the foreign potential on telephone plant in the event of contact, and to insure prompt de-energization, it then becomes necessary for the telephone plant to provide lower impedance paths to ground than heretofore and to handle increased fault currents.

In some other cases where load capacity is increased by voltage increases with no significant change in load current, the possible use of fault-current limiting devices may create a similar need for low impedance in the telephone plant in order to insure fault-current values which can be distinguished from load currents and initiate prompt de-energization of the power line. The problem of handling a wide range of fault currents in telephone plant is complicated further in some cases by the use of power system reclosers with fast–slow sequences to permit automatic sectionalization of the power loads. Such operation, of course, extends over a longer period of time than in the cases where positive and rapid single-shot interruption is provided.

Telephone System Protection

In the telephone plant, carbon block arresters which provide a low-voltage spark gap are used at subscriber premises to provide effective grounding of the telephone lines when the lines are subjected to abnormal voltages.[6] In order to minimize potential differences which might constitute fire or shock hazards, the grounding is preferably common with that used by the power system and is, of course, as low in impedance as possible.

At telephone stations served from open wire the arresters are protected against overheating by 7-ampere fuses which, in the case of very high currents or sustained currents, open and isolate the station and

Paper 56-237, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 20, 1955; made available for printing December 6, 1955.

W. R. Bullard is with Ebasco Services, Inc., New York, N. Y., and H. E. Weppler is with American Telephone and Telegraph Company, New York, N. Y.

the station protector to prevent overheating. In the case of stations served from metallic-sheathed cable, a fuseless type of station protector is used which is capable of withstanding higher currents and provides a continuous path to ground in the case of foreign voltages.

Where distribution is by means of metallic-sheathed cable, the cable sheath is grounded frequently in order to keep the impedance to ground low. Where joint with multigrounded neutral power lines, the sheath is often bonded to the power system neutral at frequent intervals to provide a low-impedance path for fault currents.

In the open-wire plant additional heavy-duty carbon block arresters are used where the plant is exposed to power lines operating at 5 kv or higher voltages in order to provide supplementary paths to ground in the event of contact. These operate after the station arresters and fuses have operated, grounding the telephone line to prevent arc over of station fuses and to provide prompt and positive de-energization of the power circuit. The protector used for many years in this application is the Western Electric *99A* protector (or other similar types) which operates to ground the telephone conductors when the impressed voltage exceeds about 3,000 volts.

Minneapolis Tests

Because of the prospect of heavier suburban power loads in their area, with the attendant problem of co-ordinating protection, the Northern States Power Company, the Northwestern Bell Telephone Company, and the Bell Telephone Laboratories in 1953 conducted a series of field tests of protector arrangements at a site near Minneapolis, Minn. This work is described in a paper by Albrecht and others.[4]

The data desired included an extension of the time–current curves for the *99A* protector into the range of higher currents than previously tested and the effects of various recloser cycles. The tests provided valuable information on the limitations of the *99A* and offered the opportunity for initial tests on an experimental protector design proposed for the heavier fault currents and for the extended duty cycles which might be expected in the future.

The Minneapolis tests also afforded an opportunity to investigate the fusing or burn-down characteristics of the common types of telephone line wires. Such characteristics become of particular significance as heavy-duty protector designs approach the point where the protector current-handling capacity may exceed the fusing points of line conductors. It was first recognized as a result of these tests that the change in impedance of telephone conductors while carrying fault currents may have a significant effect on the co-ordinated protection.

Ontario Tests

Subsequent to the Minneapolis tests, the Bell Telephone Laboratories proceeded with the development of a new heavy-duty protector, the Western Electric *118A*, along the lines of the experimental type tried at Minneapolis.

Preproduction samples of the *118A* were tested in 1954 during a series of co-operative tests conducted near Toronto, Ont., Canada, by The Hydro-Electric Power Commission of Ontario, The Bell Telephone Company of Canada, and the Bell Telephone Laboratories. That work is reported in detail in the paper by Ellis and others.[5]

The Ontario tests provided valuable information on the time–current characteristics of the *118A* protector. A limited number of tests on the *99A* were included also, to provide direct correlation between the two types. Additional data on fusing and change-in-impedance characteristics of telephone line wires and cable were also obtained to augment the earlier tests.

By means of this series of tests it was determined that the current-carrying capacity of the *118A* protector will be much greater than that of the *99A* and will exceed the fusing characteristics of the more commonly used exchange telephone line wires. Several refinements for the *118A* design were suggested as a result of the tests.

Conclusions

The protector development work and field tests of the past 2 years have resulted in a new protector design which is expected to make possible co-ordinated protection of telephone lines and high-capacity power lines, thus facilitating joint use of pole lines for such facilities.

The new protector is expected to have current-handling properties exceeding those of the most commonly used exchange telephone conductors, suggesting that in those cases any further increase in protector capacity would be unnecessary.

As the ratio of estimated fault current to load current is reduced in typical cases, it will be increasingly important to take into account the thermal characteristics of the telephone conductors in estimating the impedance of fault-current paths. There is a possibility that the thermal rise in line impedance may cause the fault current to drop below that which would insure positive de-energization of the power line.

The possibility is foreseen of cases in which the fusing characteristics of the telephone line wire would be exceeded by the estimated fault currents and in which it might be found desirable to take account of the burn-down of the telephone conductors to provide the means of removing the foreign potential from the telephone plant rather than to rely on the de-energization of the power line itself.

THE rapid growth of suburban areas in the vicinity of the larger cities has created many problems for both power and communication companies. A number of power companies have chosen to meet load growth in such areas by increasing their primary distribution voltage. Such increases in voltage have in general been accompanied by substantial increases in substation, feeder, and subtransmission capacity. These changes have in turn introduced problems concerning the maintenance and operation of overhead lines jointly occupied by the power and communication companies.

The Northern States Power Company was faced with such load growth problems following World War II in the suburban areas adjacent to Minneapolis and St. Paul, Minn. The solutions to these problems had to take into consideration the extensive joint use of wood poles with the Northwestern Bell Telephone Company in these areas.

As a result of an extensive and detailed engineering study, the decision was made to convert most of the existing 4-kv multigrounded neutral system in these areas to 12.5 kv. The conversion, which was to take place over a period of 5 to 7 years, was complicated by the fact that a great deal of open-wire telephone plant was involved. The extensive use of exchange open-wire telephone plant in these areas, most of which was on joint-use poles, was due to the relatively low population density and the extensive use of multiparty service. Economic considerations precluded replacement of much of this open-wire plant with cable in conjunction with the conversion of the power system to 12.5 kv.

The generally accepted standards of good engineering as set forth in the National Electrical Safety Code[1] provide that if telephone circuits are to be placed on the same poles or involved in numerous crossings with power circuits at voltages above 5,000 volts, a higher grade of construction should be used for the power line except where co-ordinated electrical protection is provided.

Co-ordinated protection involves the application of special protective devices to the power and telephone systems which will permit both of the following conditions to be fulfilled:

1. The power and telephone circuits are so constructed, operated, and maintained that the power circuits will be promptly de-energized, both initially and following subsequent breaker operations, in the event of a contact with the telephone plant.
2. The voltage and current impressed on the telephone plant in the event of a contact with the power conductors are not in excess of the safe operating limits of the telephone protective devices.

In view of the impracticability of providing separate lines or providing a higher grade of construction in the proposed conversion areas, it was mutually agreed that the application of co-ordinated electrical protection was the proper engineering solution.

Joint occupancy of pole lines by telephone and power companies at voltages higher than 5,000 volts is not new.[2] Practically all of the previous joint-use experience with high-capacity higher voltage distribution systems, however, involved telephone cable plant rather than open wire. Previous experience with open-wire joint use with higher voltage power systems on the other hand has been almost entirely limited to low-capacity rural-type distribution systems.[3-6]

The development in recent years of new protective devices for power systems made possible the development of a heavy-duty high-capacity 12.5-kv distribution system by the Northern States Power Company.

The demand for information concerning the co-ordination of existing telephone protective equipment with these new power system protective devices resulted in the tests discussed in this paper. These tests were conducted jointly by the Northwestern Bell Telephone Company, the Northern States Power Company, and the Bell Telephone Laboratories at Minneapolis in 1953.

Power System Characteristics

The design features of the high-capacity heavy-duty 12.5-kv distribution system, developed by the Northern States Power Company, which affect protection co-ordination are as follows:

1. The maximum permissible symmetrical fault current for a zero-impedance ground fault is limited to approximately 4,000 amperes rms for operating reasons, and the usual minimum value for a similar fault is 600 amperes. Typical fault currents for zero-impedance faults at any point on a 12.5-kv feeder main line or tap as a function of distance from the source are shown in Fig. 1. The intersection of each numbered curve with the vertical axis represents the fault current on the feeder main line at that number of miles from the substation. Fig. 2 shows the typical fault currents for 20-ohm ground faults. Curves *A* and *B* of Fig. 2 are shown on Fig. 1 to illustrate the controlling effect of fault impedance.
2. Substations are spaced from 6 to 8 miles apart with from four to six 300-ampere feeders from each substation. Fig. 3 shows a typical 12.5-kv area.
3. Each feeder main line is limited to a length of 4 miles, with full 300-ampere capacity over the whole length. Full-capacity emergency switching is provided between adjacent feeders (Fig. 3).
4. No ground fault relaying is provided at the substation at this time. This type of relaying is now under consideration but its effect on joint-use co-ordination is not expected to be significant in this situation.
5. The use of automatic circuit reclosers with dual operating characteristics (the so-called "fast" and "slow" operations) in feeder branches, or in some cases in the main lines, provides automatic sectionalizing of the feeders but imposes a heavier burden on the telephone protection system than would result from the use of fuses. This heavier burden is the result of delayed opening and up to three circuit reclosings.
6. The use of fuses instead of reclosers would preclude large-capacity feeders and in some cases would have made voltage conversion impracticable. Fuses are used, however, in short single-phase laterals where use of a recloser or sectionalizer is not justified or where open-wire joint use alone may require them.
7. The maximum demand on the single-phase laterals is generally limited to 300 kva (about 40 amperes) to permit restora-

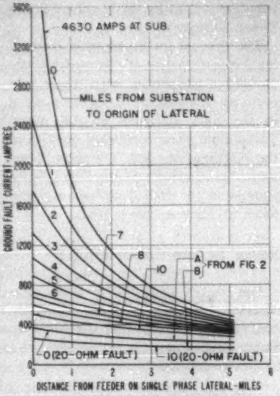

Fig. 1. Ground-fault currents for zero-impedance faults on a 12.5-kv feeder, 4/0 copper 3-phase lines with no. 6 copper single-phase laterals

tion of service with a 70-ampere recloser after loss of diversity. Selection of this recloser rating was influenced by the assumption of a 20-ohm maximum fault resistance in telephone contacts.

8. The assumption of a 20-ohm ground fault resistance results in current values which are close to main-line load currents. The phase relaying used on the feeders will not discriminate between ground fault and normal load currents. Ground fault relaying has been avoided up to the present because it is desirable to permit the feeders to operate with large unbalanced loads during emergency conditions.

Telephone System Characteristics

The voltage and current limitations of subscriber station protectors require the application of heavy-duty auxiliary protectors on open-wire exchange telephone circuits exposed to power system voltages in excess of 3,000 volts to ground. The Western Electric *99A* protector shown in Fig. 4, which is normally used in the Bell System for this purpose, consists of three cylindrical carbon electrodes enclosed in a weatherproof container and separated so that the breakdown voltage between them is about 3,000 volts rms. Two of the electrodes are connected to the telephone line wires and the third electrode is connected to ground. This must be a very low resistance ground which generally can be secured by bonding to an effectively grounded power system neutral.

These auxiliary protectors are normally installed at approximately half-mile intervals so that in the event of a contact midway between two protectors, assuming that only one protector operates, the fault impedance will not exceed 20 ohms. This value assumes a contact with the smallest size telephone conductor used on open-wire lines, *083* steel, although this size is infrequently used on joint-use lines. The fault impedance is reduced as the point of contact approaches the protector location and is zero at the protector. Consequently, for a given power system impedance the voltage on the telephone plant is proportional to the distance between the point of contact and the protector. The current, however, increases approximately inversely as this distance and may vary from 360 to 4,000 amperes for a power-telephone contact on the main line of a 12.5-kv feeder.

The current-carrying capability of the *99A* protector, published some 15 years ago, for three successive shots at 15-second intervals ranges from 600 amperes of 1-second duration to 1,800 amperes of 0.15-second duration. This was more than adequate for the open-wire joint use situations in effect at that time as the power system protection in most cases consisted of low-rated single or 3-shot fuses.

Test Objectives

As stated in the foregoing, a series of tests was scheduled for the summer of 1953 to secure the following information relative to power and telephone system protective devices which was not then available:

1. The time–current characteristics of the *99A* protector at higher current values.
2. The behavior of the *99A* protector under the duty cycles imposed upon it by various reclosers under a wide range of fault currents.
3. The capabilities of a number of other telephone protectors including several modifications of the standard *99A* and an experimental model of a new protector furnished by Bell Laboratories.
4. Data on the fusing, arcing, burn-down, and thermal characteristics of the types of telephone line wire most generally used in exchange plant.

Test Setup

The site selected for the tests was the Northern States Power Company's Gleasons Lake Substation. This substation is located about 10 miles west ofMinneapolis and is supplied from a direct tap on the 115-kv loop around Minneapolis and St. Paul. The substation was at that time a 7,500-kva 115/13.8-kv station with one express 13.8-kv tie-line to a near-by 13.8/4-kv substation and one 12.5-kv distribution feeder. Line protection consisted of station oil circuit breakers on the 13.8-kv line and the 12.5-kv feeder. Station protection consisted of a differential relay operating a high-speed grounding switch on the 115-kv side of the transformer.

The site itself consisted of several acres of ground more or less isolated from residential areas and free of trees and structures. A direct tap was made on one phase of the 13.8-kv line (which was removed from normal service for the tests) to an H-frame structure on which were mounted six reclosers, a potential transformer, and a hook-stick-operated cutout (see Fig. 5). From this structure one span of 336.4-MCM bare aluminum wire was strung at right angles to a span of telephone conductor and some 8 feet above it. I nthe actual tests a weighted contact wire from the power circuit was allowed to lie across the telephone wire or a direct connection was made from the power wire to the telephone wire. A 1-line diagram of the test layout is shown in Fig. 6.

The magnitude of the fault current was controlled by series-parallel combinations of three 100-foot spans of 48 wires each of telephone conductor, the particular wire used was *134H* steel wire. Normally, open-wire joint-use telephone plant in these suburban areas would consist of *109H* steel wire but the larger size was used in this case because of its greater thermal capacity.

In order to avoid dangerous earth potentials due to fault currents returning from the grid to the substation grounding system through the earth, one end of the grid was connected through an insulated cable directly to the substation ground bus. When telephone protectors were being tested they were inserted between the grid and the ground-return cable.

Oscillographic recordings were made of the current in the circuit and the voltage on the "load" side of the recloser with a 6-element oscillograph and with a 3-element rapid-record oscillograph. A timing wave taken from the station bus was also recorded on the 6-element instrument for reference purposes.

Test Results

The test results indicated that the *99A* protector currently available for open-wire joint use with higher voltage lines is inadequate for 12.5-kv high-capacity distribution systems similar to that de-

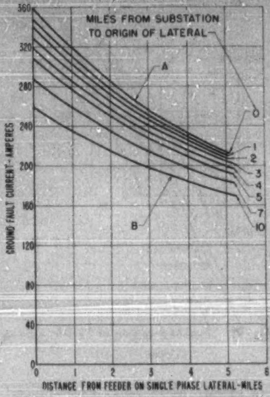

Fig. 2. Ground-fault currents for 20-ohm faults on a 12.5-kv feeder, 4/0 copper 3-phase lines with no. 6 copper single-phase laterals

veloped by the Northern States Power Company.

The data obtained in these tests indicated, however, that a heavy-duty auxiliary protector, which would be adequate for this type of joint-use construction, could be provided. Fig. 7 shows an experimental model which was tested and showed possibilities of meeting minimum performance standards.

Time-current curves derived from test data for the standard *99A* protector and the experimental model are shown in Fig. 8. These curves are based on initial values of fault current and only approximate a constant-current condition. They show currents that can be carried for indicated times without incapacitating the protector.

The time-current curve for *109H* steel wire is also shown in Fig. 8. This curve is based upon initial current values.

An important effect which was noted was the increase in resistance of the telephone-line wire due to heating. This was especially noticeable on the lower values of fault current where the fusing occurred after a relatively long period of time or did not occur at all. This phenomenon is discussed in more detail in the following.

Application of Test Results

The results of the tests had two important applications. The first is in the design of a new protector which will withstand the duty cycle imposed upon it by high-capacity 12.5-kv systems. The performance of the Bell Laboratories' experimental model was particularly encouraging in this respect. It is anticipated that the new protector will be better under most fault conditions than the types of wire normally used for exchange open-wire plant so that a path to ground will be provided until the telephone wire fuses.

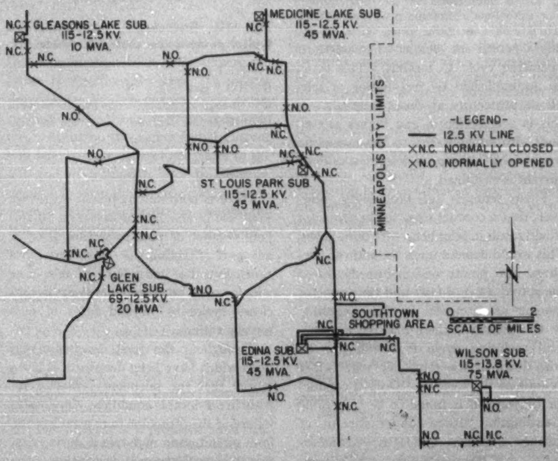

Fig. 3. Typical suburban area showing 12.5-kv main-line feeders

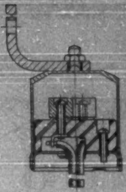
Fig. 4. Heavy-duty auxiliary telephone protector, type 99A



The other principal application of the test results is in the design of protection schemes for 12.5-kv distribution feeders. A simple example of a distribution feeder is shown in Fig. 9 and the curves associated with the various power protective devices are given in Fig. 10. Fig. 11 shows the curves of the power and telephone devices superimposed and the areas where co-ordination can and cannot be obtained may be seen. (These curves are for constant current conditions and do not take into consideration any current decay.)

For example, protection co-ordination is usually not possible in the main line of section *A* of Fig. 9. Since the station breaker will not respond to minimum fault currents (20-ohm faults), only burn-off of the telephone wire in the fault circuit in the event of low-current faults or operation of the station breaker on sustained high currents are available to open the circuit. Burn-off of a telephone wire can occur only when the cold resistance of the telephone wire is small, and where its increasing resistance does not combine with the source impedance to prevent fusing before the recloser can complete its cycle. This condition can prevail only over a relatively short distance from a telephone protector. Even if burn-off is acceptable as a means of de-energizing the contact, the proportion of section *A* in which this can occur is so small that joint use cannot, as stated, be permitted anywhere in this section. Open-wire joint use is possible on the fused laterals in this section, however, since the fuses will clear any faults on the laterals practically instantaneously. Likewise, open-wire joint use is possible on the taps protected by the 70-ampere reclosers. In this case, the minimum fault current would have to be checked against the recloser time-current cycle.

In section *B*, the minimum fault current problem on the main-line portion (protected by the 140-ampere recloser) is different from the main line in section *A* in that a reduction in the 20-ohm fault resistance to some lower value, with its corresponding increased fault current,

C—Experimental model protector

might permit the recloser to complete its operating cycle to lockout. This could be accomplished by installation of telephone protectors at closer intervals. If this is accomplished, any higher ground fault current value up to the maximum would lock out the recloser if the fault current is sustained.

There remains the probability, however, that a contact close to the protector would result in telephone-wire burn-down. This would depend upon the ratio of telephone and power system impedances at the actual point of fault and the protector spacing as discussed in the preceding. In this situation there may be no practical reclosing cycle that will prevent burn-down of the telephone wire before lockout of the recloser. Only if conductor burn-down is found to be acceptable co-ordination (from the standpoint of economics, safety, and other considerations), can open-wire joint use be considered in this situation.

There is nothing to prevent open-wire joint use in any lateral beyond a 70-ampere recloser or fuse in section *B* or in any part of section *C*. Tests were quite conclusive that burn-down of telephone wire is not to be expected in the faster recloser cycles or beyond fuses of customary ratings.

Throughout the fault clearing operations which have been described, it is essential that the telephone protector remain in serviceable condition. Obviously, failure of the protector to re-establish the fault circuit or to maintain it during current flow would prevent completion of the recloser cycle to lock-out.

G—Experimental model protector

It should be pointed out that the curves of Fig. 11 should be used for the layout of co-ordinated protection schemes only if the phenomenon of current decay is recognized and taken into consideration. Fig. 12 shows a typical current-decay path plotted from test data for *109H* steel wire with an initial fault current of 410 amperes. It can be seen that the co-ordination with a 70-ampere recloser is questionable since the current drops below the time–current curve of the recloser before the recloser reaches lock-out. Actually, the higher initial current will tend to shift the recloser curve to the left and co-ordination may be possible, depending upon the specific circuit conditions. Further information concerning this characteristic is given in the appendix.

Conclusions

The following conclusions are based on the results of these tests:

1. The need for a heavier duty auxiliary telephone protector is greater than originally anticipated.

2. Development of a protector with time-current characteristics better than the characteristics of the telephone-line wire normally used on joint-use lines is feasible.

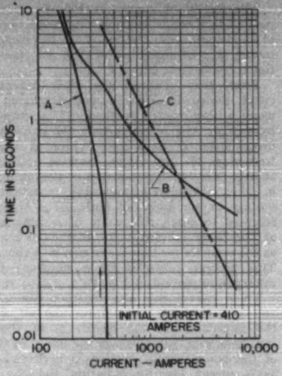

Fig. 12. Current-decay curve from actual test data showing questionable co-ordination with recloser

A—Path followed by decreasing current due to wire heating (109H wire)
B—70-ampere recloser: 13 AB total time to lock-out
C—Fusing current 109H wire (initial current)

3. Consideration should be given to the protection derived from the removal of the supply voltage from the telephone plant by burn-off or fusing of the telephone conductor when prompt de-energization of the power circuit is impracticable.

4. An important characteristic which had not previously been recognized was the fault-current decay resulting from the increase in resistance due to heating of the telephone-wire portion of the circuit. This characteristic is the controlling factor in determining fault-current magnitudes and durations in many situations and is increasingly important on high-capacity distribution systems. Future investigation of this phenomenon is necessary in order to evaluate its effect on co-ordination of power and telephone protective devices.

5. Minimum as well as maximum values of power-system fault currents and their duration as well as maximum load currents must be controlled if satisfactory co-ordination is to be achieved without affecting normal service standards of both power and telephone systems.

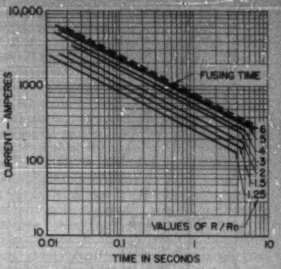

Fig. 13. Calculated time–current curves of 109H steel telephone wire for constant R/R₀ ratios

R_0 = resistance at 20 C
R = final resistance

6. High-capacity higher-voltage power-distribution systems generally involve a wide range of fault currents in addition to larger load currents. This, together with the more frequent use of automatic reclosing on faults, requires the closest co-operation between power and telephone engineers in the design of joint-use plant. Any compromise which is necessary to permit open-wire joint use must not be at the expense of co-ordinated protection.

Appendix. Calculated Curves of Current Decay in Steel Wire

It is desirable in many cases to apply the largest circuit recloser with delayed settings that a power-telephone contact will permit. To accomplish this, it is necessary to determine as accurately as possible the minimum fault current which the fault circuit can sustain throughout the reclosing cycle to lock-out. In order to establish such lower limits for one type of commonly used telephone-line wire, the relative change in resistance of *109H* steel line wire was calculated as a function of time for a number of fixed current values. The following energy equation was used:

$$I^2R_0[1+\rho(\Delta T)]t=\frac{WC_M(\Delta T)}{0.239}$$

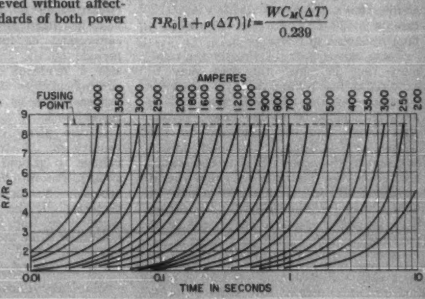

Fig. 14. Resistance ratio versus time of 109H steel telephone wire for constant currents

R_0 = resistance at 20 C
R = final resistance

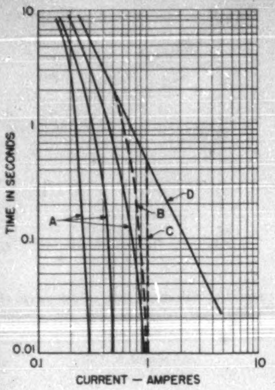

Fig. 15. Calculated constant-current fusing curve and maximum current-decay curve for 109H steel telephone wire

A—Maximum-current decay (constant voltage at fault)
B—Intermediate current decay
C—Sustained current (zero fault resistance)
D—Fusing time for sustained currents

where

I = assumed sustained current value in amperes
R_0 = resistance of unit length of wire at 20 degrees centigrade (C) in ohms
ρ = thermal coefficient of resistivity of material
ΔT = increase in temperature during interval
t = time interval in seconds
W = weight of unit length of wire in grams
C_M = specific heat of material

The equation was solved for t for various values of I assuming that ρ and C_M are constants for each temperature interval.

Energy losses from radiation and convection were neglected, so the resulting curves show minimum limits rather than actual values. The effects of the galvanizing were also neglected. Fig. 13 shows the results of these calculations.

It should be noted that the calculations assume that the wire will fuse at a temperature of 1,550 C. This corresponds to a final resistance of 8.5 times R_0.

These curves indicate directly the minimum time in which this wire may be expected to fuse for any fault for which the impedance of the telephone wire itself is negligible compared to the power system impedance. This can occur only in the section of telephone circuit immediately adjacent to the protector, generally within 200 feet. In this interval, the circuit recloser must complete its cycle to lock-out in less time than indicated by the curves if fusing of the telephone-line wire is to be prevented.

The family of curves in Fig. 14 were plotted as a convenience in the calculation of the current-decay curves. They represent merely a rearrangement of the information presented in Fig. 13.

From these curves, the time–current curve shown in Fig. 15 was developed, using a step-by-step method. This step-by-step method assumes that the current drops instantly to a lower value at the beginning of any time interval. The change in resistance to arrive at this value is then calculated assuming constant voltage at the point of fault. The time required to reach this value of resistance at the lower current value is then taken as the ordinate for that lower current value. This process, repeated for a number of intervals, is plotted in Fig. 15.

These curves are also limiting values, and arise from the assumption that all of the impedance in the circuit is in the telephone wire. In this case the impedance of the power circuit portion is neglected, as is energy loss by radiation and convection. These curves indicate the maximum current decay which can take place because of heating and the resultant increase in resistance of the telephone wire. Actual current values as a function of time will vary from sustained initial currents to the maximum decay shown, depending upon the relative magnitude of the fixed power-circuit impedance and the increasing telephone-wire resistance.

The curve for an intermediate rate of current decay is also shown in Fig. 15.

Example

For a fault midway between two protectors spaced at half-mile intervals on *109H* steel wire, the actual fault resistance in the telephone circuit is approximately 10 ohms at 20 C. With the assumption that only one protector operates, the initial current should be between 500 and 700 amperes (see Fig. 1), depending upon the impedance of the power system. At these values of initial current, the curves in Fig. 16 indicate that more than 200 amperes will be available to operate the circuit reclosers at the end of 5 seconds. It should be noted that burn-down or fusing of the telephone wire could not necessarily be prevented, depending upon the choice of recloser cycle for this particular application.

The use of these calculated curves tends to give pessimistic results with regard to de-energization of the power circuit since no allowance is made for heat loss from the wire by radiation and convection, or for cooling during open periods of the recloser cycle. There is also a tendency for the recloser time–current curve to shift to the left since the recloser curve is plotted on a constant-current basis.

If the power contact occurs in the vicinity of the telephone protector, the voltage to ground at the contact would always remain below the 3,000 volts necessary to break down an adjacent protector. If the fault occurs at a point more remote from a protector, the current-resistance drop along the telephone wire between the fault and the operating protector may rise to 3,000 volts or more, which may operate the adjacent protector. This would provide a parallel path to ground and would result in added current in the power-circuit protective device, which would provide an additional safety factor in operating the power system recloser, circuit breaker, or fuse.

Discussion

Frank W. McStay (Line Material Company, Milwaukee, Wis.): The participants in the Minneapolis tests deserve to be complimented upon their valuable contribution.

At one point the paper comments on the burden imposed on the telephone protection system when automatic oil circuit reclosers are used, the burden imposed being the duration of fault current flow. It might be desirable to note that recloser operating characteristics today are quite versatile and that the burden imposed when reclosers are used would to a considerable extent depend upon the operating sequence and characteristic selected when applying the reclosers.

Whether ground-fault relaying should be avoided is perhaps a moot point. There are advantages to be gained by its use. As an example, a 100-ampere recloser will trip at 200 amperes. Assume that the normal load on such a recloser is 80 amperes. For ground trip pickup at 100 amperes the unbalance required for tripping would therefore be 125% of the regular load current. In other words, the minimum tripping current with ground-fault relaying would be only one-half that required when ground relaying is not employed. Yet the unbalance required to trip this particular recloser would be greater than the normal full-load current.

As a matter of terminology in connection with the fault current decay, whether the recloser time-current characteristic should be said to shift to the right or to the left depends on the reference fault current values held in mind, initial fault current, or that which exists sometime after the fault initiation. Shifting the characteristic to the right would indicate slower operation. And, of course, if the recloser characteristic as shown for constant currents is not shifted, then, because of the current decay involved in this application, the point on the characteristic which would indicate the actual recloser opening time would lie to the left of the initial fault current.

The time-current characteristic for the 140-ampere recloser shown in Fig. 11 should not extend past 6,000 amperes.

E. G. Albrecht, E. W. Christoferson, A. E. Dietz, and **J. C. Slothower:** Mr. McStay is quite correct in stating that a very wide choice of recloser operating characteristics is available to the power system designer. However, the choice of these characteristics and operating cycles is limited in any particular case by the operating requirements of the particular power feeder. Obviously, an increase in the number of fast operations will reduce the burden imposed upon the telephone protection system, but it introduces other problems in the power protection scheme.

With reference to the suggestion that ground-fault relaying be incorporated as a possible solution, it would appear that in the example chosen a 100-ampere recloser with an 80-ampere load, there would be no particular difficulties in protection co-ordination in this case. An 80-ampere load would involve maximum fault current of probably not much more than 1,200 amperes. With reference to Figs. 1 and 15, it can be seen that the maximum fault currents of this magnitude would, in general, involve neither burn-down nor an appreciable amount of current decay. Nevertheless, ground-fault relaying offers attractive possibilities and may permit protection co-ordination in many cases where it would not otherwise be possible.

The statement that the recloser curve shifts to the left is based upon the final value of fault current. If the initial value of fault current is considered, then the recloser will require a longer time to operate with current decay, and it could be considered that the operating curve shifts to the right. The authors feel that information concerning the amount of this shift would be extremely useful in laying out power system protection schemes involving open-wire telephone contacts. Allowances for this factor may permit the use of a larger recloser or longer operating cycle.

WHEN POLES are jointly used by power and communication utilities, or the two types of plant are on separate pole lines but are in situations of close proximity, the possibility of accidental contact between the two types of plant must be recognized. The first line of defense against such occurrences is to minimize the probability of contact by means of adequate construction and clearance standards, as covered by the National Electrical Safety Code in the United States or the Canadian Electrical Code in Canada.

Notwithstanding the grade of construction employed, however, the possibility of accidental contact will still exist due to abnormal weather conditions or accidents. To ensure the safety of persons and to limit damage to plant and property in the event of contact, certain co-ordinated protection features are incorporated in the design of the jointly used plant. Positive and prompt interruption of the contact current to the communication plant, either by de-energization of the power circuit or by some other means, and limitation of the voltages on the communication plant to the range of safe operating characteristics of communication protective equipment, constitute the modern view of the objectives of co-ordinated protection.

When the telephone plant consists of open-wire conductors, and the power conductors to which the telephone plant is exposed are operated at a voltage-to-ground below 3 kv, the protection furnished by the conventional station protection apparatus is usually sufficient. The fuse at the subscriber's station protector is in series with a small air gap which breaks down to ground in the event of contact. The consequent flow of fault current through the fuse causes it to operate and isolate the station. However, in joint use, or occasionally at crossings, when the power supply conductors operate at greater than 3 kv, auxiliary protectors are connected between the communication wires and an effective ground at intervals along the line. If a multigrounded neutral is present on the line, the preferred ground connection for the auxiliary protectors is to the multigrounded neutral as illustrated in Fig. 1.

The gaps between electrodes in the model of these auxiliary protectors used heretofore (*99A*) are such that they break down at about 3,000 volts rms. This value was chosen in the design of the *99A* protector because voltages below this

value will not maintain an arc in the subscriber's protector fuses after they have blown. Breakdown of the auxiliary protector follows the operation of the subscriber's protector, and effectively quenches the arc in the fuses.

A contact between a supply wire energized at over 3,000 volts-to-ground and a communication conductor results, therefore, in the breakdown of a near-by auxiliary protector gap, with consequent flow of power-system ground fault current. If the design of the co-ordinated protection scheme is sound, the impedance in the fault path, including the part of the communication plant involved, is low enough to permit the fault current to operate the power system protective device, such as a fuse or recloser, and hence effect prompt and positive de-energization. The low impedance in the communication part of the fault path, assured by the proper spacing of the auxiliary protectors, also limits the voltage appearing on the communication plant.

Need for Improved Protector

The auxiliary protector, like all such devices, has an inverse time–current characteristic beyond which its destruction takes place. Obviously, under the present co-ordination scheme, this characteristic must exceed that of the power-system protective device or the protector will be destroyed before the power device operates, and de-energization will not be realized.

With the trend towards greater loads on power distribution circuits, the ratings of fuses and other protective devices have, in many cases, risen to the point where co-ordinated protection is unattainable with the telephone auxiliary protector used heretofore. This is illustrated by the fact

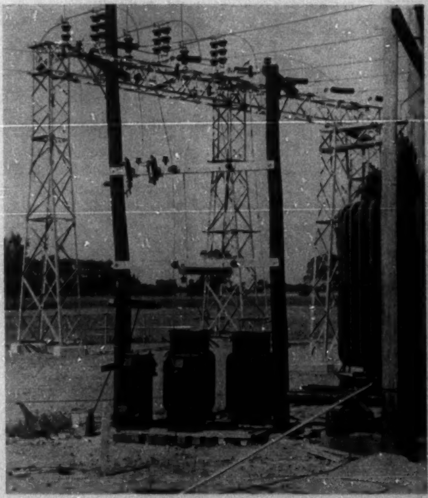

Fig. 3. Transformers and disconnect switches used in tests

that line-to-ground fault currents for modern rural distribution stations, such as those of The Hydro-Electric Power Commission of Ontario, will vary from 1,000 to 9,000 amperes, depending upon the characteristics of the supply system. The power protective devices normally used on these rural distribution systems have time-current characteristics which often exceed the current-carrying capabilities of the *99A* auxiliary protectors.

Rural distribution lines in Ontario, which are fed from modern distribution stations varying in capacity from 2,000 to 4,000 kva at 8 to 12.5 kv, have coordinated protection based upon a combination of reclosers, sectionalizers, and fuses. The trend is to use reclosers on feeders and sectionalizers on laterals, especially for long lines where fuse maintenance is costly. Generally, reclosers, rated from 50 to 100 amperes, and set for one fast and three retarded operations, are used on rural feeders.

Several years ago it became apparent that the savings and other benefits of the joint use of poles could no longer be fully realized unless a better telephone auxiliary protector could be provided.[1] The conflict between increasing loads on the power system and the economic desirability of jointly used plant finally progressed to the point where Ontario Hydro realized that an improved telephone protector was required in the near future or jointly used plant would have to be curtailed and existing joint use reduced. Accordingly, in 1952, Ontario Hydro suggested to The Bell Telephone Company of Canada and Bell Telephone Laboratories that the possibility of supplying an improved protector be investigated. On the basis of similar suggestions arising in the United States, a series of field tests was made in Minneapolis, Minn., in 1953 to evaluate certain aspects of the problem.[2]

New Protector Design

Part of the Minneapolis tests were devoted to the determination of the time-current characteristic of the standard *99A* protector for times and currents in line with the modern demands of joint use. The results indicated that the *99A* was inadequate for many of the applications desired. Preliminary models of a new protector were also tested at that time and as a result, the conclusion was reached, that a protector, adequate for present-day conditions, could be developed.

Realizing the necessity of providing a protector capable of handling the necessary currents long enough to perform its intended function, the engineers at the Bell Telephone Laboratories therefore produced a new design along the lines indicated by the tests at Minneapolis.

This new protector in its final form has been coded the *118A* protector and will replace the *99A* protector in the Bell System. It consists essentially of three wedge-shaped carbon electrodes arranged on a ceramic base as illustrated in Fig. 2. The gaps in the new protector are adjusted so that breakdown occurs at approximately 2,000 volts rms. For normal operation, an electrode is connected to each of the conductors of a telephone open-wire pair, and the third electrode to an effective ground, such as a power system multigrounded neutral (see Fig. 1).

Protector Test Layout

In order to determine the time-current characteristic of the new protector, a series of tests was performed cooperatively by Bell Telephone Laboratories, The Bell Telephone Company of Canada, and The Hydro-Electric Power Commission of Ontario at the Ontario Hydro transformer station near Brampton, Ont., during the summer of 1954.

This station, known as the Pleasant Transformer Station, was a new installation with only one feeder in service, and space was available in the relay building for all controls and equipment required

for the tests excluding, of course, the outdoor transformers and circuit breakers. The line-to-line symmetrical short-circuit capacity on the 27-kv feeder was 300,000 kva. This was sufficient capacity so that the tests produced negligible disturbances on the 27-kv system.

Essentially, the power circuit consisted of the 27-kv supply, a 27-kv breaker, a 3-phase 60-cycle 1,000-kva transformer (rated 27.6-kv delta to 2,400/4,800 volts delta or 4,160/8,320 volts wye) and, when required, two 100-kva distribution transformers (rated 4,800/2,400 to 575 volts). In addition, two easily visible air disconnect switches were used to isolate and ground the circuits and equipment in the working area between tests. The transformers and disconnect switches were installed as shown in Fig. 3.

The magnitudes of the test currents were controlled solely by the insertion of transformer reactances as required. This method of controlling current magnitudes resulted in substantially constant test currents throughout the duration of each test. Arrangements of the transformer connections, as shown in Fig. 4, made it possible to obtain test currents from 150 to 3,500 amperes.

In order to simulate single- and multiple-shot characteristics of distribution fuses and oil circuit reclosers, a special control panel was constructed for the 27.6-kv breaker used to switch the fault current. Fig. 5 shows a schematic of the control panel circuit. Essentially, this circuit consisted of two timing relays, one of which, *T2*, was energized through an auxiliary switch on the breaker to control the duration of fault current. The other, *T1*, provided the desired time delay between reclosures. A stepping relay *ST*, used in conjunction with the time-delay relays, limited the number of reclosures as desired. In the event of failure of the relay controls, a back-up relay, *SMT*, was provided to trip the breaker to prevent over-heating of the transformers.

The telephone network is illustrated in Figs. 6 and 7 and consisted essentially of a 2-pole H-structure with a third pole 50 feet distant to support protector and wire test samples. A rope and sheave arrangement was provided to permit raising and tensioning the wire samples. Burndown tests on several types of communication conductors were performed by means of this arrangement. Fig. 8 shows a test on one of the protector samples.

As a safety measure, the test area was enclosed by a fence and no one was permitted to enter this area until the power circuit had been opened and the test circuit connected to ground.

Current and voltage measurements were made on two oscillographs. A photographic record of each test was made on a 16-millimeter movie camera equipped with a telephoto lens, and still photographs were made of all samples after test. Data on each of the tests were recorded on a printed data sheet.

Protector Test Results

Each of the protector tests involved a given magnitude of current applied for a certain length of time, and these two parameters, current and time, were varied independently in successive tests until a predetermined amount of damage, a condition called the "critical damage point," was reached. The criteria of critical damage were:

1. The gap spacing should not have increased to the point where breakdown would not occur on a subsequent fault.
2. The carbon electrodes should be held securely in place and be free from cracks.
3. The base material should be intact.
4. The mechanical parts of the protector (clamping nuts, and so on) should not be damaged to the extent that the structure would be weakened.

Fig. 9 illustrates representative amounts of damage to the protector before, at, and beyond the critical damage point. Sufficient protectors were tested at each time-current combination to provide adequate sampling.

(*Continued from page 230*)

The new protectors intended for these tests were manufactured with the same type of electrode material and the same size of lead-in wires as used in the standard *99A* protector. It was apparent, after very few tests, that the new protectors were not performing as well as the experimental models tested previously at Minneapolis. Upon investigation, it was discovered that the only significant difference between the two lots was in the type of carbon employed. The electrodes used in the construction of the experimental models had been made from carbon which was softer and contained a much higher percentage of graphite than does the standard carbon that is used in all other Western Electric Company protectors. In order to determine the precise difference in the two types of carbon, a quantity of electrodes was fabricated of the graphitized carbon and time–current characteristics were determined for both types. The results are plotted in Fig. 10, and indicate the marked superiority of the graphitized carbon as electrode material in high-current applications where a relatively large gap is involved and flaking of the electrode surface is therefore not a serious problem.

It will be noted that there is a discontinuity in the graphitized-carbon electrode curve at approximately 1,000 amperes. At and beyond this current point the lead-in wires fused before the electrodes or clamping nuts were damaged appreciably. In an attempt to determine the capability of the electrodes beyond the fusing point of the leads, some of the protectors were modified to provide heavier leads. The results obtained are indicated by the dotted section of the curve.

The time–current critical damage curve of the new protector was determined by a series of single-shot tests. This curve, therefore, does not allow for the short recovery intervals that occur during the process of normal recloser operation. Supplementary tests indicated that, with 1.5-second de-energization periods between current applications, a total current application time approximately 10 per cent greater than the time of a single-current application will result in the same protector damage.

From observations made of the protector performance there appears to be a critical time, dependent upon current, when the arc, previously confined in the electrode gap, expands to the clamping nuts and consumes them. This was arbitrarily called the "arc transition point" and occurs at approximately 90 per cent of the time required for critical damage. In other words, destruction of the protector is not a linear function of time but occurs rather suddenly after the protector has carried current satisfactorily for some period of time. This effect is illustrated on the protectors shown in Fig. 11, and is also very apparent in the moving pictures made of the tests. Evidence of this effect was noted by the observers as a change in the sound of the arc.

It is concluded, from a consideration of the foregoing phenomenon, that the protector will withstand an unlimited number of operations provided that:

1. The arc transition point is not exceeded on any one application of current.
2. A comparatively long period of time is allowed between repeated power protective-device sequences to permit adequate cooling of the protector.

Line and Drop Wire Tests

The development of a new protector of higher current-carrying capacity introduces a new problem in co-ordinated protection. Data obtained during the 1953 Minneapolis tests[2] indicated that the new protector capability characteristic would probably exceed the time–current fusing characteristics of some of the more commonly used communication exchange line wires. Because of the increased time–current characteristics anticipated in the new protector applications, the change-in-impedance characteristic with current and time of the line wire becomes of greater importance in co-ordinated protection than has hitherto been the case. Tests were therefore performed in Ontario to determine:

1. The simple time–current fusing characteristic of the line wires under steady fault-current conditions.
2. Their change-in-impedance as a function of current and time.

A typical oscillogram showing voltage and current traces is given in Fig. 12, and illustrates the basic test data used to derive the fusing and change-in-impedance characteristic.

Tests of this nature were made on drop wire and on steel, copper-steel, and copper telephone line wires. The physical characteristics of the line wires tested are given in Table I. The data obtained are presented in Figs. 13 to 17.

Engineering Applications

The advantages derived from the use of heavier leads, as shown by Fig. 10, resulted in the specification of no. 8 American Wire Gauge copper leads for the *118A* protector rather than no. 10 leads as are used in the *99A*. Several minor modifications of the protector design have been made since the field tests in an effort to improve the characteristic of the protector at currents below the fusing point of the no. 8 leads.

It will readily be seen by a comparison of the characteristics for the *99A* and the *118A* protectors (Fig. 18) that the development of the new protector will broaden considerably the field of joint power and communication facilities. The new protector provides, in fact, time–current characteristics that are adequate for the great majority of joint-use situations. This is also illustrated in Fig. 18, where the protector characteristic is contrasted to the fusing characteristics of the more commonly used types of communication wire. It will be noted that the protector characteristic everywhere lies beyond that of *109H* steel wire and beyond *104* copper-steel wire except in the range of currents below approximately 400 amperes.

Present practice, as embodied in the National Electrical Safety Code in the United States and the Canadian Electrical Code in Canada, is that, in the event of accidental contact between higher-voltage power conductors and telephone conductors, the power supply must be positively and promptly de-energized unless higher grade construction is employed. The separation of the two facilities due to the fusing of the communication conductor has not heretofore been considered as a means of securing co-ordinated protection under the codes. Consequently, the engineering of joint-use situations with the new protector would, under present practice, only extend up to the fusing point of the telephone conductor.

A new problem in this regard has to do with the change-in-impedance of the communications conductor during fault conditions; a problem more apparent owing to the longer fault duration times allowable with the new protector. This means that not only must the initial fault currents be computed, but also the magnitude of the change-in-current as a function of time. An example is given in the appendix in which this changing current effect causes a shift in the point of operation of the power system protective device to a part of its operating characteristic where burndown of the line wire appears to be a possibility. Burndown does not actually occur, but the example illustrates the necessity of a check of each joint-use section.

The point has been raised in discussions of joint-use engineering problems that in certain well-examined situations burndown of the communications conductor might be accomplished with the assurance of the same degree of safety as de-energization of the power supply would afford. As yet, no field studies have been instituted to prove or disprove this and, in addition, the economics of the problem have not as yet been examined. Such a scheme would again increase the field of joint-use endeavor.

The second example given in the appendix shows an engineering computation based on the assumption that burndown of the communications conductor is found to be a satisfactory alternative to de-energization. In such a case assurance is needed that the line wire will, in fact, fuse before a predetermined amount of damage is done to the protector.

Safety Uses of the New Protector

The breakdown voltage of the new protector has been set at approximately 2,000 volts to permit its use on lower voltage power systems to reduce the likelihood of power contact voltages remaining on the open wire and presenting a possible hazard to linemen. There are no special problems in engineering its use on lower voltage systems to de-energize the power system or to hold down the voltage on the communication wire to a reasonable value. However, the application and administration of this protector purely as a safety item has not as yet been established. It may be that certain lines, because of age, tree conditions, and weather conditions, have a bad history of power contacts. These, then, would be the cases where, in the judgment of the joint-use engineers involved, additional protection would be of some benefit.

Conclusion

As can be seen from the foregoing, the new protector constitutes a major improvement over the *99A* protector and over a large range has even greater current-carrying capacity than the line wires with which it is normally associated. These facts indicate the effectiveness of the new device in securing co-ordinated protection in many situations where the *99A* type would be inadequate.

Application of the new protector to joint-use situations involves a number of problems which have not yet been fully resolved. Further investigations are proposed which, it is hoped, will lead to the establishment of suitable practices based upon the solutions and may, in due course, permit the presentation of a fourth paper in this series (in addition to references 1, 2, and this paper) dealing with the subject of co-ordinated protection applications.

Appendix

As explained in the foregoing, the development of the *118A* protector has enlarged considerably the possible field of joint power and communication open-wire facilities as it may be used on many systems whose fault currents or durations are expected to be greater than could be handled by the *99A*. With these increased currents and times, the effect on the fault current of the change-in-impedance of the communication line wire becomes of greater importance than has heretofore been recognized. In brief, the job of the joint-use engineer becomes not only larger, but more complex also.

An effort has been made to devise graphical methods by which the engineering of many joint-use lines can more easily be done. Two examples will be given to show how this method works. The examples are not to be thought of as typical or even as representative of the problems encountered in the engineering of a joint-use line, as each line will be different from all others, and will be a continuously variable thing itself, from the substation to the end of the joint section. The only tools used commonly in each example are the line wire curves presented in Figs. 13 and 14.

Example 1

A 2-wire single-phase multigrounded neutral power system is fed by a 10,000-kva transformer with a phase voltage of 13.8 kv. The power conductor is no. 4 steel-reinforced aluminum cable and protection is furnished by a 100-ampere fuse. The power line is, in part, on joint poles with a pair of *109H* steel telephone open-wire conductors. The *118A* protectors are installed every 1,000 feet on the open-wire pair and the protector ground lead is connected to the neutral conductor.

Assume that a solid contact is made between the power phase wire and one of the telephone wires 8,500 feet from the transformer. The contact occurs midway between two *118A* protectors, but assume that only one of them operates. Other fault-current paths to ground, such as those through station protectors, will be ignored in this example. It is then necessary to know whether the 100-ampere fuse will blow or the line wire fuse.

The total initial impedance of the fault circuit is as follows:

$$\begin{aligned}\text{Power impedance} &= \text{transformer} + \text{power line} + \text{neutral}\\ &= j1.14\omega + 8.5(0.529 + j0.283) + 2.0 + j0\\ &= 6.49 + j3.54 \text{ ohms}\end{aligned}$$

$$\begin{aligned}\text{Telephone impedance} &= 0.5(8.5 + j1.1)\\ &= 4.25 + j0.55 \text{ ohms}\end{aligned}$$

$$\begin{aligned}\text{Total initial impedance} &= 6.49 + j3.54 + 4.25 + j0.55\\ &= 10.74 + j4.09 \text{ ohms}\end{aligned}$$

The initial current for a potential of 8 kv to ground is therefore:

$$I_0 = \frac{8{,}000}{10.74 + j4.09}$$

$$= 696 \text{ amperes}$$

From this initial current, a series of successive approximations on Fig. 13 yields a number of new values of current at later times, caused by the thermal change-in-impedance of the line wire.

These approximate currents and times are as follows:

Current, Amperes	Time, Seconds
696	0
640	0.16
593	0.29
516	0.55
407	1.15
335	2.07
248	4.35

Fig. 19, then, shows the fusing characteristic of *109H* steel line wire, the total clearing time characteristic of the 100-ampere fuse, and the plot of the fault current as a function of time. The conclusion might be drawn from this figure that not only would the 100-ampere fuse fail to blow, but also, the fault current might fall low enough to come to an equilibrium point below the minimum fusing current of the line wire.

The immediately recognizable fallacy in this argument stems from the fact that both the wire and the fuse characteristics were derived from data gathered from constant-current tests and in the simulated example the current is far from constant. Recourse must therefore be made to a graph on which the amounts of energy required to fuse the wire and the fuse link are shown as functions of current. See Fig. 20. In the range of currents of interest, the fusing energy of the line wire is an independent function of current, as shown by the straight line in the figure. The fuse link however has considerable variability in the amount of energy needed to cause it to blow at different currents. At this point it should be admitted that the product of current squared times time is merely proportional to energy, but the problem is greatly simplified if this adjustment will be admitted.

To this figure is then added the curve of energy input to the system as a function of current. This is obtained by graphically integrating the area under a curve on which the square of the fault current is plotted as a function of time. It is now possible to adjust the fuse link curve to take into account the changing fault current. As in all the steps previously outlined, this is an approximate thing, but if sufficient attention is applied, the results should be fairly sound. The adjustment in the curve is achieved by finding first a number of current points at a number of equally spaced points in time, starting at the moment of contact. Time intervals of 0.25 second were used in the example, and the current values were read from Fig. 19. At the initial current point, the fuse-link fusing energy is as shown at the 696-ampere intercept on Fig. 20. At the second current point (610 amperes in the example) the adjusted value of fuse-link fusing energy is approximately equal to the value at current point *1*, plus one half the difference between the values at current points *1* and *2*. Then, the adjusted value at current point *3* is approximately equal to the adjusted value at point *2*, plus one-half the difference between original points *2* and *3*. The remaining points on the adjusted curve are found in the same manner.

It will be seen from Fig. 20, that the 100-ampere fuse will blow and clear when the current has decreased to a value of approximately 360 amperes or at about 1.67 seconds. The time value may be obtained from Fig. 19.

Example 2

A 2-wire single-phase, multigrounded neutral power system is fed by a 10,000-kva transformer with a phase voltage of 13.8 kv. The power conductor is no. 4 hard-drawn copper. Overcurrent protection is furnished by a fuse whose characteristic lies beyond the fusing characteristic of the telephone protector and can therefore be eliminated from consideration in this example. The joint-line wire is *104* copper-steel with *118A* protectors spaced each half mile. The ground electrode of the protectors is connected to the power neutral.

Assume that a solid contact is made at a point midway between *118A* protectors, at a distance of 20,000 feet from the transformer. As before, assume that only one of the adjacent protectors operates and any other current paths to ground will be ignored in this example. Assume also that it is deemed necessary for the line wire to fuse before the protector reaches the "arc transition point," a condition described in the text, or before the protector leads fuse. Fig. 21 shows the characteristics of the line wire and of the protector for the conditions described.

The total initial impedance in the fault circuit is then:

$$\begin{aligned}\text{Power impedance} &= \text{transformer} + \text{line} + \text{neutral}\\ &= j1.14 + 20(0.332 + j0.257) + 4.0 + j0\\ &= 10.64 + j6.28 \text{ ohms}\end{aligned}$$

$$\begin{aligned}\text{Telephone impedance} &= 1.32(2.37 + j0.35)\\ &= 3.13 + j0.46 \text{ ohms}\end{aligned}$$

$$\begin{aligned}\text{Total initial impedance} &= 10.64 + j6.28 + 3.13 + j0.46\\ &= 13.77 + j6.74 \text{ ohms}\end{aligned}$$

The initial current for a potential of 8 kv to ground is therefore:

$$I_0 = \frac{8{,}000}{13.77 + j6.74}$$

$$= 521 \text{ amperes}$$

The fault current as a function of time may again be found by a number of successive approximations on Fig. 14. These are:

Current, Amperes	Time, Seconds
521	0
499	0.76
477	1.68
442	3.30
378	6.75
332	12.25

When these values are plotted in Fig. 21, it would appear that the "arc transition point" would be reached before the line wire fuses. However, the use of the energy relationships and the subsequent adjustments for changing fault current, as shown in Fig. 22, lead to the conclusion that the line wire will fuse before the protector "arc transition point" is reached. This occurs when the fault current has decreased to a value of approximately 360 amperes, or at a time of 8.2 seconds.

It should be pointed out in conclusion that in each of the examples given, the actual co-ordination of power and communication protective equipment was determined. Obviously this cannot be determined on the basis of the time–current characteristics only, as had been done in the past.

Discussion

M. Fraresso (Hydro-Electric Power Commission of Ontario, Toronto, Ont., Canada): From a power utility point of view the final objectives of joint use of poles is the simplification and standardization of procedures which will result in greater economics without loss of safety and reliability. The development of the new protector has greatly enhanced the possibility of securing these objectives but now further evaluation of co-ordination protection is required to take full advantage of the recent developments. It is now possible to secure co-ordination of the power protective devices with the more commonly used communication line wires, provided line wire burndown removes the power potential from the communication circuit. Example 1, Appendix, indicates that this co-ordination is obtained even when it is assumed only one *118A* protector operates for a power cross in the middle of the joint use section.

The authors are to be congratulated on their presentation of a timely subject, and the work that has been accomplished to date. They have mentioned the possibility of employing the principle of "burn-down providing satisfactory co-ordination." This revolves around the problems of ensuring that the burn-down occurs in the vicinity of the power cross hence securing de-energization of the communication circuits, as yet no general conclusions being established. It would appear desirable to give further consideration to this approach as it may provide a simple solution to a complex problem.

It might be well to speculate some of the reasons whereby burn-down could occur, subject to confirmation by actual tests. These reasons are:

1. Contact area will be small, resulting in a relatively high contact resistance compared with the resistance of communication wires.
2. Oxides on the surface of the conductors will tend to increase the contact resistance causing localized arcing at the point of contact, and high arc temperatures in the neighborhood of 6,500 degrees Fahrenheit could melt the communication conductor at the point of contact. This situation would be further enhanced at high current values because of the spattering effect of metal (based on the welding characteristics of 1/8-inch rods when the arcing current exceeds 200 amperes).
3. The effect of movement of the power wire across the communication wire will result in deformation and pitting of the communication conductors and increasing the possibility of burn-down at the point of contact.
4. Provided power cross occurs between two joint-use protectors, the second protector will operate after the first has burned clear. This will subject the point of contact to prolonged arcing.

If burn-down becomes accepted as a criterion of co-ordination, considerable extension of joint use with the new protector could be obtained especially if the low- and high-current ends of the present protector damage curve could be improved to ensure co-ordination with *104* copper steel line wire over the whole range of currents.

For joint use near power substations, the *118A* protectors would be required at intervals less than the usual spacing of 1/2 mile in order to limit plant rise to 3,000 volts. With the added restriction of increased impedance of communication wire as a function of current and time, as illustrated in the paper, it may become necessary further to reduce spacing of *118A* protectors drastically to ensure that the maximum plant rise of 3,000 volts would not be exceeded. It would therefore be desirable to remove this restriction on plant rise by adopting an improved fuseless subscribers' protector and relying on co-ordination with the drop wire time–current fusing characteristics similar to the co-ordination obtained for cable protection.

Where the drop wire can be used for co-ordination, if a power cross occurs at a point having several subscribers located between it and the *118A* protector, the communication conductor between the power cross and the protector will be subject to an additional 10 per cent of the I^2t equivalent heating per subscriber (for *109* steel) than the remainder of the joint use section. This is based upon the I^2t equivalent thermal capacity of the drop wire compared to that of the line wire.

If it were possible to remove the restriction on plant rise by allowing communication line wire burndown to constitute co-ordination, a significant step would be taken in simplifying joint use engineering requirements without loss of safety and reliability.

H. M. Ellis, J. W. Phelps, C. L. Roach, and **R. E. Treen:** It is safe to say that the objectives of both power and telephone companies as regards the safety and reliability of their separate functions are very much the same. In both utilities the objective is ever-increasing service to more and more customers at a constantly reducing cost with a consistent margin of safety. Naturally, an extension of open-wire joint use is one method whereby considerable savings can be achieved. The introduction of the *118A* protector does much for the extension of joint use, as it is now possible, under present practice, to engineer joint-use lines up to the fusing point of the communication line wire, taking into account, of course, the effect of the changing line wire impedance under fault current conditions, as illustrated briefly in the paper.

There are, however, a large number of power distribution systems that must use protective apparatus whose time–current characteristics are greater than the fusing characteristics of communication line wire. If these systems are to be constructed jointly with telephone plant, interruption of any fault current flowing on the telephone conductors must be accomplished through burn-down of the line wire. The reasons listed by Mr. Fraresso in his discussion would seem to assure the safe burn-down of telephone plant, and the same lines of thought were followed prior to the tests at Minneapolis (see reference 2 of the paper). However, a limited number of tests there indicate otherwise. The results of these few tests, which were not reported in the paper because of their inconclusive nature, have been rationalized as follows:

1. The high thermal conductivity at the contact point afforded by the usually heavier power conductor causes heat to be quickly conducted away from the point of contact. This effect appears to be greater than the combined effect of arcing and high contact resistance at the contact point. In the line-wire fusing tests where the power wire was allowed to drop on the line wire, the line wire did not fuse within perhaps an inch of the contact point. It did, however, become hot enough in several cases to become welded to the power conductor. The sequence of events might have been this: The heat of the initial arc at the contact and of the concentrated current through that small portion of the wire caused that part of the wire to become plastic. The weight of the power wire then caused it to be imbedded in the line wire. Finally, the heavier power wire conducted the heat away from the contact point, causing the two wires to be welded together.
2. If the telephone line wire has been nicked by wire pullers, pliers, etc., not however to the extent that its strength is appreciably reduced, there will be localized heating at the constricted point which elevates the temperature at that point faster than the rest of the wire and causes the wire to fuse at that point only. This latter effect was so pronounced that considerable care had to be taken in the placing of the wire for test so that it would fuse uniformly.

Since the few tests performed at Minneapolis indicate the possibility of the welding of the two conductors at the contact point, or the fusing of the line wire at some remote point, there may be considerable effort necessary to investigate the effects of power contacts on typical field installations. In addition to these technical points, there are further intangible questions such as the telephone customer reaction to the service outage.

Assume next that a satisfactory solution is found to the foregoing problems so that there need be no worry about the actual physical separation of power and telephone conductors. There must then be assurance that the fault current will not flow for such a period of time that the increased resistance of the line wire causes the fault current to drop below the minimum protector operating or line wire fusing current. In the second example listed in the paper, it is apparent that if more telephone wire had been in the circuit, the initial current would have been lower, the rate of change of current with time would have been more pronounced, and the end result would have been the destruction of the protector before the fusing of the line wire. The obvious conclusion to be drawn is that unless some engineering effort is put into the layout of the telephone protection system, the system must necessarily be conservatively designed. In this case, the cost of the protection may well offset the savings in engineering effort.

It should further be pointed out that the graphical determination of the results in each of the two examples in the paper is an approximation and tests are necessary to prove the feasibility of the graphical method. Such tests would also more closely define the protector capability at the lower currents to show if further modification is necessary.

On the question of a fuseless protector for higher voltage joint-use lines, it was considered in 1950 that such would be feasible at rural telephone stations which were also served by multigrounded neutral power systems and where power and telephone were commonly grounded. Active development effort on the problem, including the design of the protector, was begun 2 years ago and is still continuing. It is safe to say that the protector can be made at increased cost over the fuseless protector now used on stations served by metallic sheathed cables. In either case, there will still be a fusible element in the subscriber's circuit, namely, the terminal cable conductors and bridle wires.

The administration of fuseless protectors at stations on open-wire lines may yet prove to be a greater problem than the design of the device. This is due to the fact that careful attention must be paid to the ground to which the protector is connected. This is important for two reasons: The magnitude of the fault current that flows through the station protector is in part determined by the resistance of the station ground, and the potential difference between the power and telephone networks in the subscriber's home is proportional to the impedance between the two grounds. In the ideal case both utilities are grounded to an extensive public water-piping system with very low impedance to remote earth. A contact, therefore, causes considerable current to flow into the ground, blowing the station fuse or the fusible element in the drop wire run. The current, however, does not cause a dangerous rise in potential at the station with respect to remote earth, neither does it cause potential differences to exist between the power and telephone systems in the home. Unfortunately, many of the stations served by open wire do not have water systems. Bonding of the telephone ground electrode to the multigrounded neutral ground must then be resorted to in order to minimize potentials between the power and telephone wiring in the station.

A Magnetic Amplifier Switching Matrix

D. KATZ
ASSOCIATE MEMBER AIEE

By using conventional high gain or bistate magnetic amplifiers as building blocks, switching networks may be derived which perform many computer or control functions. One such network which has been built and tested is a 4-digit binary-to-decimal translator. This translator was designed to provide a display in decimal numbers of binary-coded information. Basically a switching matrix made up of simple self-saturating magnetic amplifiers, this translator illustrates both the matrix technique and an advantageous application. The translator matrix operation, the specific bistate magnetic amplifier building blocks used, the decimal displays obtained, and their individual and combined characteristics are discussed in this paper.

Although magnetic core switching array applications in pulse circuits have been discussed in the literature,[1–4] the use of magnetic amplifiers to switch continuous power (rather than pulse power) has received little attention. In general, a bistate magnetic amplifier may be viewed as a contactless switch having some functional similarities to a relay. Without any moving parts, such a switch electrically isolates inputs and outputs, can provide high power amplification, and can be electrically set or biased to switch at a precise net signal value appearing in several control windings. In a manner similar to the application of magnetic cores in pulse-switching arrays, such bistate magnetic amplifiers may also be used in switching matrices. The matrix form and the building block magnetic amplifier used depend, naturally, upon the function performed, the inputs used, and the desired outputs. The specific matrix discussed in this report, a binary-to-decimal translator, acts, in effect, as a multiposition switch which distributes energy to any one of a number of positions in response to signal information. The translator accepts 4-digit binary-coded numbers on four leads and a common return, and it performs such translation and amplification that an easily read decimal number display is obtained from the 10-lead output with the use of either a 10-element neon gas tube or 10 filamentary lamps.

The translation problem arises from the need to present digital computer data in an illuminated decimal number display. With the binary computer involved, the number selected for display is converted to parallel binary-coded decimal so that each decimal digit of this number appears on four leads as a 4-digit binary-coded word. For each decimal digit there is then required a further translation from the binary-coded decimal to one out of 10 decimal signals with which to light indicating lamps or devices. This is accomplished by a magnetic amplifier-switching matrix or translator. The 4-digit binary-to-decimal conversion table in Fig. 1 shows the binary inputs and the required translation. As obtained from the computer logic packages, a binary "1" signal has an average value of 1.4 volts. The binary "0" is the absence of any signal or zero volts.

The operation of the magnetic-amplifier translator matrix to select one of 10 outputs in response to the binary inputs is described in the following section. Two types of magnetic-amplifier building blocks which have been used in such a matrix are discussed in the section "Bistate Magnetic Amplifier Switches." Discussion of decimal displays and translator characteristics, and the conclusions follow in that order.

Magnetic Amplifier Translator Matrix

For each decimal digit in the display, the associated binary to decimal translator has 10 possible 4-digit binary inputs as shown in the table of Fig. 1. With each binary input a unique one of 10 bistate magnetic amplifiers in a matrix is triggered ON while the others are held OFF. Only the fired (or ON) bistate unit transfers electrical power to its output lead so that for each binary input only one of 10 output leads is energized. The energized lead then causes a decimal number to be displayed. The schematic of such a matrix is shown in Fig. 2.

Fig. 2 shows 10 bistate magnetic amplifiers with their control windings arranged in a 4-by-10 matrix. The eliminated control windings, which would have filled the matrix, are not needed because the selection of the matrix is one of 10 inputs rather than one of 16 bits available from a 4-digit binary word. In this instance, half-wave magnetic amplifiers consisting of one core with a power winding, several control windings, and a bias winding are shown as the bistate units of the matrix. The dots indicate winding polarities, with current which enters the winding through a dotted end called positive. Thus, with the indicated bias current direction and bias winding polari-

ties, all the biased units have negative ampere turns bias. The bias windings are weighted by having N_B, $2N_B$, or $3N_B$ turns as indicated in Fig. 2. All control windings have equal turns (N_C).

To explain the operation of the matrix, the bistate units may be assumed to have an idealized transfer characteristic as shown in Fig. 3. The output state (ON or OFF) is determined by the net control or the algebraic sum of the ampere-turns of all the control and bias windings on a bistate unit. Any binary digit 1 input causes an average control current I_c to flow through the control windings of the associated column in the direction indicated in Fig. 2. Therefore, on a per-unit basis with N_cI_c as a control unit, a binary 1 signal in a control winding is a ± 1 control where the sign is determined by the polarity of the control winding. With a binary 0 input there is no current flow. The bias current (I_B) is set so that $|N_BI_B| = |N_cI_c|$, or on a per-unit basis, the bistate units having N_B turns are biased to -1, those with $2N_B$ turns to -2, and those with $3N_B$ turns to -3. As seen in the transfer curve of Fig. 3, any unit with zero or greater net control is fully ON. Any unit with -1 or less net control is fully OFF. Now, observing the bias values and the control winding polarities, the table of Fig. 4 can be constructed showing the net control (bias plus control input) on every bistate unit for each of the 10 binary inputs. For example, with a (0, 0, 0, 0) binary input, all the bistate units will have some bias value (-1, -2, or -3) except for the decimal 0 unit which has no bias. Consequently, only the decimal 0 unit, having zero net control, is ON. For any other input the 0 unit is driven off because all of its control windings have negative polarities. For a (0, 0, 1, 1) binary input, only the decimal 3 unit will have zero control while all others are negative. For instance, unit 7 will have a bias of -3, a $+1$ control in the 2^0 column, and a $+1$ in the 2^1 column, yielding a net control of -1. The table, Fig. 4, which tabulates all these values, clearly shows that for each of the 10 binary inputs, a unique one of the 10 bistate devices is driven on.

The particular switching matrix described switches electric power suitable for directly operating the output displays. The two output states of the bistate units here employed are a continuous voltage or practically no voltage output as derived from the a-c power supply. In the pulse circuit magnetic core matrices, which are more widely discussed in the

literature[1-4] the output derived from a read-out current pulse is a voltage pulse or no pulse indicating one of two core flux states.

Assuming a bistate magnetic-amplifier transfer characteristic as in Fig. 3, which can be closely approximated in practice, one soon realizes that switching matrices utilizing such building blocks embody several desirable characteristics. Foremost, the switching is relatively insensitive to changes in the amplitude of the power supply voltage. Secondly, the output voltage of the nonselected units are negligible in comparison to the selected unit's output voltage. Switching ratios (the ratio of the output voltage at the ON state to the output voltage of the OFF state) of from 5 to 500 are common for magnetic amplifier bistate units. Further, there is considerable margin for the amplitude of the binary input signals. The matrix is also extremely economical of power and shows every indication of being economical in size and weight.

Bistate Magnetic Amplifier Switches

Recent papers and articles[5-7] both here and abroad about bistate magnetic amplifiers attest to the increased interest in such devices. In the translator matrix described, two types of magnetic amplifiers were used as the switching elements. These are the half-wave circuit, Fig. 5, and the doubler circuit, Fig. 6. The transfer characteristics, obtained from particular designs of the circuits which were used in laboratory matrices, are shown alongside each circuit. These curves are plotted on a per-unit basis (normalized) with the binary 1 input control current value (I_c) as the control unit and the zero control output load quantity (I_{L0} or V_{L0}) as the load unit.

From these transfer curves, it may be seen that the switching units of Figs. 5 and 6 are bistate by virtue of the digital-control input which is a 0 or $a \pm 1$ per-unit control. Actually, the points on the steep part of these characteristics are stable. If it were desirable, as in an analogue-to-digital conversion, the doubler circuit of Fig. 6 could be designed so that there would be truly no stable points between the two output states. This is commonly done by adding positive external feedback as is shown in Fig. 7. With increasing amounts of positive feedback the slope of the steep part of the transfer curve (AB in Fig. 6) increases through infinity and becomes negative, i.e., the curve theoretically bends back upon itself. However, since the points of infinite or negative slope are unstable, the transfer characteristic takes on the form shown in Fig. 7.

With a digital-control input, high-gain magnetic amplifiers, such as those of Figs. 5 and 6, make very satisfactory switching elements. Since a control signal is either a 1 or 0 on a per-unit basis and the bias is some integral multiple of the 1-per-unit control, these magnetic amplifiers can have only one of two outputs, either OFF or ON. However, for the translating matrix of Fig. 2, the closer the switching unit's characteristic is to the ideal characteristic of Fig. 3, the closer will the permissible variation of the binary input signals approach a theoretical maximum of ±20.8 per cent (%).

The half-wave circuit of Fig. 5 uses only one core and one diode, but necessitates a high impedance to alternating current in every control and bias loop in order to minimize the transformer action between load and control meshes. In the steep region of the transfer curve, AB in Fig. 5, the gain or slope varies inversely with the induced a-c components in the control meshes. Consequently, in the translating matrix, Fig. 2, which uses half-wave magnetic amplifiers, there is required an inductor, L_1, L_2, L_3, L_4, and L_5, in each control mesh. Series resistors, R_1, R_2, R_3, R_4, and R_5, are padding resistors to compensate for winding resistance variations and to bring the loop resistance up to a desired value. The output of the half-wave circuit is, of course, half-wave recitfied alternating current. Since the Inditron gas tube display requires a direct voltage on the selected element, and since it was desirable to minimize the number of cores and diodes, the half-wave circuit was used in the translating matrix with a gas tube decimal display as shown in Fig. 2.

A balanced 2-core magnetic amplifier like the doubler circuit of Fig. 6 permits the use of low-impedance control meshes

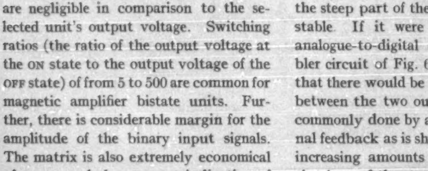

Fig. 5. Half-wave circuit

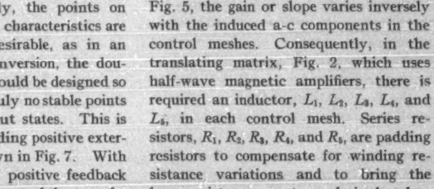

Fig. 7. Doubler circuit with external positive feedback

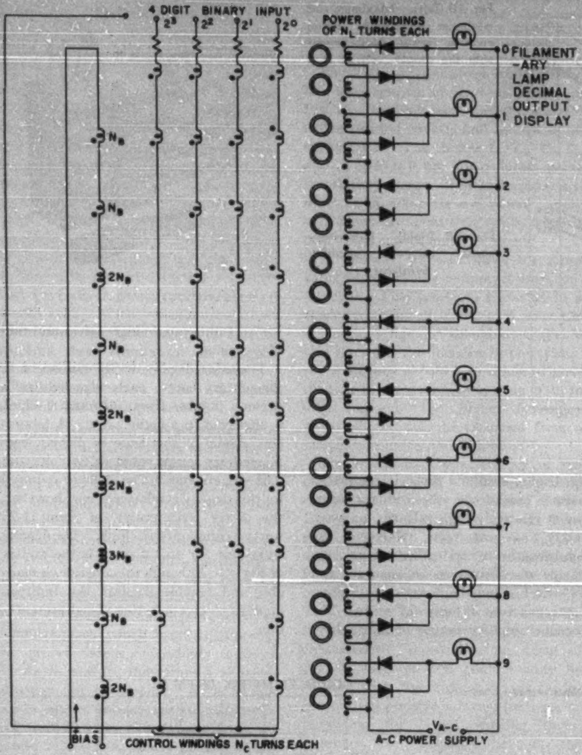

Fig. 8. Translator matrix

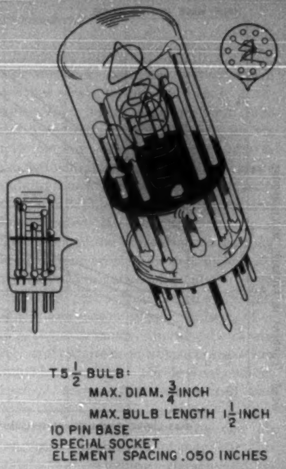

Fig. 9. National Union G1-10 Inditron neon decimal display tube

because the induced fundamental and odd harmonics of the a-c supply are bucked out in the control loops. Physically, this magnetic amplifier has two tape-wound cores each having an a-c power winding on it. These are then stacked and common control and bias windings are wound around the two stacked toroids. The output of the doubler circuit is alternating current. To provide a d-c output, two more diodes would be required for a bridge connection in the output circuit. However, for filamentary lamps the a-c output is satisfactory and the doubler circuit of Fig. 6 was used in a translator matrix with a lamp display as is shown in Fig. 8. The translator matrices of Figs. 2 and 8 are the same in principle and differ only in the type of magnetic-amplifier switch circuit used.

The doubler circuit eliminates the need for chokes in the control loops, does not severely restrict the number of control winding turns, and lends itself to the incorporation of positive external feedback. The last two factors permit very high-gain or true bistate magnetic amplifier operation.

The switching ratio of both the magnetic-amplifier circuits discussed here is a function of the number of power turns and the load impedance, for these largely determine the OFF-state output voltage. The switching ratio of the half-wave circuit, operating into a high-impedance load (51,000 ohms) in the translator, is close to six with the design values used. This ratio is more than adequate because the gas display tube's high breakdown and extinction potentials act to discriminate between ON and OFF switch output states. The doubler circuit, operating into a low-impedance filamentary lamp load (100 to 700 ohms), has a switching ratio in the order of 200. The filamentary lamp in the display requires a switching ratio of about 15.

The magnetic amplifier switches discussed are closely akin to magnetic-core switches used in pulse circuits. The former, however, use a continuous a-c power supply or drive to obtain a continuous ON or a zero OFF electrical output for the switch states, while the latter use a single-pulse drive to obtain a pulse or no-pulse indication of the switch states. Both types of switching elements have exceptionally long life, are reliable, and have large-power handling ability. The switching magnetic-amplifier's speed of response is, of course, limited to one or more cycles of the a-c power supply frequency. Although practically usable upper limits for the power supply frequency have not been investigated, there are indications that difficulties will be encountered at over 50 kc.

Decimal Displays

Two different devices were selected to obtain the illuminated decimal number display. One of these, a gas tube, such as the National Union Inditron, is preferred at present because of the clarity of the display obtained. This 10-element neon tube, with each element formed into

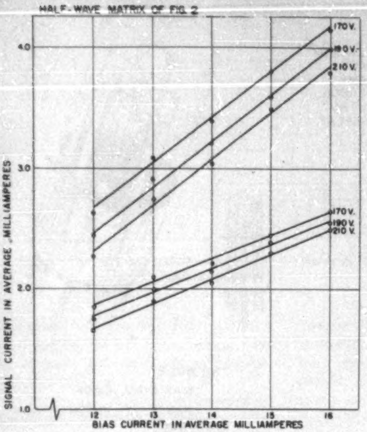

Fig. 10 (left). Maximum and minimum permissible signal currents versus bias current with the supply voltage as a parameter

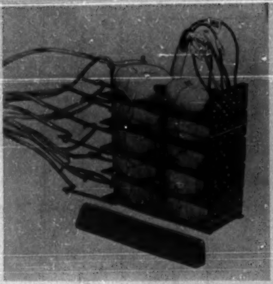

Fig. 12 (right). Laboratory model magnetic amplifier translator

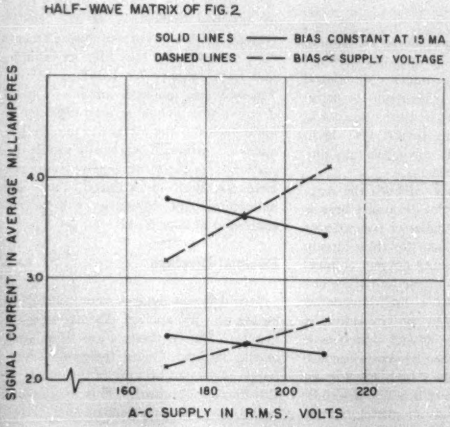
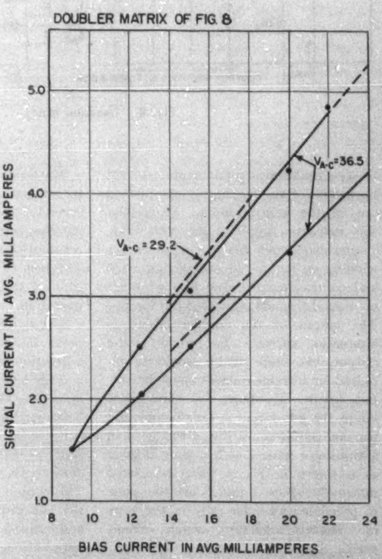
a decimal number from 0 through 9, is pictured in Fig. 9. With the half-wave rectified output of the half-wave translator matrix, the selected element is held about 125 volts rms more negative than the other elements. The selected element becomes a glowing cathode, the other elements act as shared anodes, and a well-defined, easily read decimal number display results. Since it requires a gaseous breakdown, the Inditron operates at relatively high voltages, approximately 250 peak volts. However, the high-breakdown and extinction voltages provide discrimination between ON and OFF switches and the power consumption of the gas tube is only 0.2 watt. The magnetic-amplifier matrix of Fig. 2 driving an Inditron provides a clear and reliable display.

The other display device consists of 10 filamentary lamps, each edge lighting a decimal number from 0 through 9 which is engraved in a lucite plate. A laboratory model of this type of display uses filamentary lamps rated at 28 volts and 0.04 ampere rms. The voltage required for this display is relatively low; however, the power consumption of about 1.25 watts is comparatively high. The driving translator for this display is the matrix of Fig. 8. Although this provides a readable and reliable display, the Inditron appears to give a better visual presentation.

Fig. 11 (below). Maximum and minimum signal currents versus a-c supply voltage

Fig. 13 (right). Maximum and minimum signal currents versus bias current





Translator Characteristics

The translator matrices of Figs. 2 and 8 using half-wave and doubler building blocks, have been built and tested. Since the Inditron display was preferred, a mock-up of a 5-digit decimal display with five half-wave translator matrices and five gas display tubes was assembled and demonstrated. For comparative purposes, one model of the doubler translator matrix has been built and operated. The specific designs of both types of matrices for which characteristics are given here operate with the same inputs. The binary 1 is 1.4 average volts and the binary 0 is zero volts. With a maximum current drain from the signal source of 4 milliamperes, these translators are designed for a nominal binary 1 signal current of 3 milliamperes average. The a-c power supply is 400 cycles per second.

Typical operating characteristics of a half-wave translator matrix with an Inditron tube are shown in the curves of Figs. 10 and 11. From the curves of maximum and minimum signal currents versus bias current (Fig. 10), it is seen that at 15-milliampere average bias and with a supply voltage of 190 volts rms, the binary 1 input signal current may vary between 2.38 and 3.62 average milliamperes. For a nominal binary 1 input signal current of 3 milliamperes, which is set by choosing the proper values of padding resistors R_1, R_2, R_3, and R_4, this means a ±20.6% tolerance for the inputs. With an a-c power supply voltage variation between 170 and 210 volts, this signal margin becomes ±15%. A clearer picture of the translator's insensitivity to a-c voltage amplitude is given in the plot of permissible signal currents versus the alternating voltage, Fig. 11. The solid lines are for a constant 15-milliampere bias and the dashed lines are for bias proportional to the a-c supply voltage.

Other pertinent electrical characteristics of this translator may be listed as follows:

1. Frequency—A 5% variation in the frequency (380 to 420 cps) of the supply voltage has a negligible influence on operation.

2. Power consumption—The a-c power input required is less than 1/2 watt per translator.

3. Temperature—Temperature compensation over a range of −50 to +60 degrees centigrade can be made implicit in the design, for the temperature change in bias current can compensate for the change in signal currents.

4. Response Time—Switching from one decimal digit to another takes about 0.01 second with a 400-cycle power supply.

Physically, a laboratory model of the half-wave matrix appears as shown in Fig. 12. In production such units would utilize printed circuits and be cast in an epoxy resin. The chokes L_1, L_2, L_3, L_4, and L_5 of Fig. 2, are not included in the translator package. The packaged translator for a 400-cycle a-c power supply would measure about $1^7/_{16}$ by 3 by 3 inches and weigh approximately 1 pound.

At present, an equivalent translator using a 4,000-cycle a-c supply is being constructed. This promises to result in a space reduction of about 40% over the 400-cycle design. Although unsought in this instance, this increase in power supply frequency should also result in a reduction in switching time from 0.01 to 0.001 second. The higher frequency power source may be obtained from a magnetic-coupled multivibrator.[8,9]

The operating characteristics of the doubler matrix with a filamentary lamp display are shown by the curves of Fig. 13. At a 16-milliampere average bias, with a 36.5-volt rms 400-cycle supply, and again considering 3 milliamperes average as the nominal signal, the signal margin is slightly more than ±10%. This could be increased by increasing the switching unit's gain so that its transfer characteristic approaches the ideal of Fig. 3. Greater gain could readily be realized with the doubler circuit by incorporating positive external feedback or increasing the signal winding turns. However, the difference between the signal margins of the half-wave and doubler matrices (±20.6% versus ±10%) is not due to any difference in transfer characteristics but to a-c induced effects in the control loops of the half-wave matrix which beneficially increase its margins. However, these induced effects, which are limited by the chokes, L_1, L_2, L_3, L_4 and L_5, must not be allowed to become too large, for there would be a concomitant loss in gain in each of the half-wave switching units. When this loss in gain is sufficient to move the point B on the transfer characteristic of Fig. 5 to the left of the -1 per-unit control, the translating matrix does not function properly.

The doubler matrix requires an a-c input power of 2 watts with the filamentary lamp using about 1.25 watts of this. Such a matrix would package in much the same manner and size as the half-wave matrix and would not require control loop chokes.

Conclusions

Basically, this report described a magnetic-amplifier switching matrix which switches power to one of 10 leads in response to a binary input on four leads and a common return. Such a matrix may employ any of several suitable magnetic-amplifier circuits as the bistate building block. Two circuits, the half-wave and doubler circuits, were used and demonstrated in laboratory matrices. The output of the translating matrix may be used to power devices such as indicating lamps or a gas display tube. These translators permit wide margins for input signals and power supply voltage, offer large power economy, are rugged and reliable, and require no more space than other equivalent devices. The decimal number displays derived are well defined and easily read.

This translator demonstrates one advantageous application of magnetic amplifiers as switching elements. Certainly, in switching circuits where switching times of less than 1 millisecond are not required and where continuous rather than pulse power is to be switched, bistate magnetic amplifier switches have much to offer and present such broad possibilities that their use for other applications in place of more conventional devices appears well worth consideration.

Measurements on High-Speed Magnetic Servo Amplifiers with 2-Phase Motor Load

W. A. GEYGER
MEMBER AIEE

Synopsis: Measurement of steady-state characteristics and transient-response time of high-speed magnetic servo amplifiers with 2-phase motor load offers two special problems:

1. The output current of a magnetic amplifier with rectangular-hysteresis-loop core material represents a peculiarly truncated sine wave which consists of a fundamental (60- or 400-cycle) component and an array of harmonics having relatively large magnitudes. The 2-phase motor, however, responds only to the fundamental component of this output current multiplied by the sine of the actual phase angle between it and the substantially sinusoidal line-field current of the motor. Thus, in this case, conventional methods for measuring output-input characteristics by means of a separately excited wattmeter are not always applicable.

2. The transient-response time of modern forms of magnetic amplifiers is in the order of 1 to 4 half-cycles of the power-supply frequency. Therefore, for studying the dynamic properties of such high-speed amplifiers it will be advisable to employ a transient analyzer which produces a synchronous square-wave signal voltage and permits, also with higher power-supply frequencies, direct visual observation of a stationary pattern on a dual-beam oscilloscope.

This paper is concerned with the solution of these two problems. At first, it describes the basic principle and the advantages of the "torque-balance method" which permits direct measurement of magnetic-amplifier output in terms of the "equivalent sinusoidal output voltage" for stalled-motor operating conditions. Then, it illustrates the use of a novel form of square-wave signal-voltage transient analyzer with a "magnetic switch" which consists essentially of a special saturable-reactor circuit producing a synchronous unidirectional current with nearly rectangular waveshape. When applying this analyzer, a dual-beam oscilloscope displays the wave forms of input and output voltages of the magnetic amplifier under test simultaneously on a common time base in such a way that these wave forms are exhibited on a long-persistence screen as a stationary pattern. Thus, it is possible to study the effect of various circuit-parameter changes on actual speed of response and to determine optimum design. Finally, this paper gives results of additional measurements on the circuit under test. Measurement of bandwidth on a 400-cycle position servomechanism illustrate the dynamic performance of the circuit when operated in connection with a phase-sensitive rectifier in a closed-loop servo system. Measurements concerning reduction of asymmetry zero-drift errors make it evident that such errors are reduced to about 1/40 of their original values as a result of the application of a large amount of electric negative feedback resistance-coupled into the control-circuit loop.

DURING the past 10 years, a considerable part of the research and development work on magnetic amplifiers has been conducted toward the application of such amplifiers for the control of small 2-phase induction-type reversible motors. These motors are extensively used in various kinds of servomechanisms because of their reliability, rapid response, and absence of commutator sparking. Magnetic servo amplifiers, based upon various forms of full-wave or half-wave push-pull circuits, have been successfully applied in the realm of instrumentation and automatic control; and they have proved to be particularly suitable for use in high-performance instrument-type servos for remote positioning applications. Another interesting possibility consists in employing such amplifiers in the operation of high-speed self-balancing potentiometers and bridge networks.

The designer, when investigating steady-state characteristics and transient-response properties of high-speed magnetic servo amplifiers with 2-phase motor load, faces two special problems. At first, he must consider the fact that the output current of a magnetic amplifier with rectangular-hysteresis-loop core material is, in general, highly nonsinusoidal. It represents a peculiarly truncated sine wave which consists of a fundamental (e.g., 60- or 400-cycle) component and an array of harmonics having relatively large magnitudes. The separately excited 2-phase motor, however, responds only to to the fundamental component of this output current multiplied by the sine of the actual phase angle between it and the substantially sinusoidal line-field current of the motor.

An obvious method for measuring this fundamental component consists in applying a single-phase wattmeter which is separately excited by means of a sinusoidal auxiliary current of fundamental frequency. This method, however, does not consider those effects on the operation of the motor which are caused by phase-angle variations in the magnetic-amplifier output circuit. It is, therefore, desirable to provide another method, the basic principle of which includes the actual effects of these phase-angle variations on the operation of the 2-phase motor.

The second problem resides in the fact that the transient-response time of modern forms of magnetic amplifiers is in the order of 1 to 4 half-cycles of the power-supply frequency. For this reason it is advisable to employ a transient analyzer which produces a synchronous square-wave signal voltage and permits direct visual observation of a stationary pattern on a dual-beam oscilloscope. However, application of the simple magnetic-amplifier transient analyzer employing a synchronously operated mechanical switch[1] is limited to low power-supply frequencies where a mechanical switch can be operated in a reliable way. It is, therefore, necessary to provide another arrangement which may be used equally well in the range of higher power-supply frequencies, for example those derived from magnetic frequency multipliers.[2]

This paper describes measurement of steady-state characteristics and transient-response time of a typical single-stage design of a high-speed magnetic servo amplifier with 2-phase motor load. It suggests application of the torque-balance method which permits direct measurement of magnetic amplifier output in terms of the equivalent sinusoidal output voltage for stalled-motor operating conditions. Then, it illustrates the use of a novel form of square-wave signal-voltage transient analyzer with a magnetic switch which consists essentially of a special saturable-reactor circuit producing a synchronous unidirectional current with nearly rectangular waveshape. This arrangement

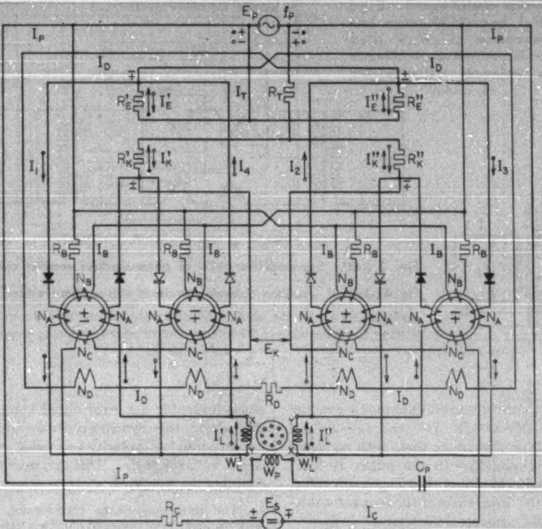

Fig. 1. Circuit diagram of the self-balancing half-cycle-response magnetic servo amplifier with separately excited 2-phase motor

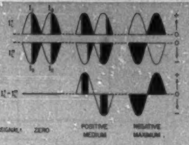

Fig. 2. Variations of the average values of the four half-cycle pulses, I_1 to I_4, and wave forms of the resultant motor currents I_L', I_L'', and $I_L'-I_L''$ for the typical example that, with no-signal conditions, the firing angle of the four saturable-reactor elements is 90 degrees

has proved to be a valuable tool for experimental studies on the dynamic properties of high-speed magnetic amplifiers, particularly those having full response to a sudden change of input signal within the time of 1 half-cycle of the power-supply frequency.

The Circuit Under Test

Although the measurements described in this paper are basically applicable to various types of high-speed magnetic servo amplifiers with 2-phase motor load, it is necessary to describe one representative form of such an arrangement for illustrating the measurement technique.

The circuit of Fig. 1 is a typical example of a full-wave high-speed magnetic servo amplifier with separately excited 2-phase motor. This single-stage arrangement, a self-balancing magnetic amplifier,[3,4] employs special combination of internal positive magnetic feedback and negative electric feedback. In accordance with the fundamental principle of single-stage self-balancing magnetic amplifiers, self-saturation and additional positive external feedback produce an effectively infinite gain that is highly degenerated by negative feedback resistance-coupled into the control-circuit loop.

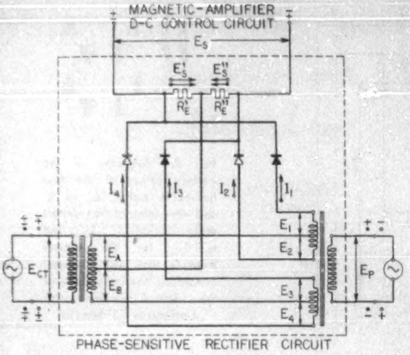
In the direct-voltage-controlled push-pull circuit of Fig. 1, the polarity-reversible signal voltage, E_S, is balanced by means of several voltage components. These components are supplied in time sequence by the polarity-reversible voltage drop, E_K, across feedback resistors R_K', R_K'' and by additional voltages induced in the control-winding elements from nonfired cores during their gating half-cycles. As a result of this fact, the balanced control circuit demands practically no energy from the d-c signal source, e.g., a phase-sensitive rectifier; and the effective input resistance is about 100 to 1,000 times higher than the actual input-circuit resistance.

In order to reduce size and weight of the amplifier, the comparatively large power-supply transformer used in similar arrangements[3,5,6] has been eliminated. This was made possible by employing a special form of a double-bridge type of self-saturating push-pull amplifier with two pairs of feedback resistors, R_K', R_K'' and R_E', R_E'', in the line circuit. In this case, the gate windings, N_A, of the four saturable-reactor elements are divided into two equally rated parts, which are insulated from each other.

The circuit arrangement of Fig. 1 has been operated from a 115-volt 400-cycle line voltage in connection with a standard-type 400-cycle 2-phase motor. This squirrel-cage motor has two separate 58-volt control windings W_L', W_L'' (maximum output power 3 watts or 20 volt-amperes) and the 115-volts line-field winding with series capacitor C_P securing proper phasing of auxiliary current I_P. Of course, it is also possible to replace the motor control windings W_L', W_L'' by two separate primary windings of an additional transformer and to connect the control winding of the motor across the secondary winding of this transformer. Application of an output transformer prevents the quiescent currents (load currents I_L' and I_L'' with no-signal conditions) from flowing through W_L' and W_L'' and corresponding heating of the motor. It also permits impedance-matching of the circuit components. It is to be noted, however, that the output transformer should be constructed of high-remanence material to preclude reaction of this transformer upon the saturable cores from stored-energy feedback.[6]

The 2-mil Orthonol[7] tape cores of the four saturable-reactor elements have the following dimensions: outer diameter, $1^3/_8$ inches; inner diameter, $1^1/_8$ inches; tape width 1/4 inch. Each core has four multilayer toroidal windings of enamel-insulated copper wire, no. *31* (Brown and Sharpe gauge): output windings, $N_A =$ 2 by 2,000 turns (2 by 50 ohms); bias windings, $N_B = 400$ turns (12 ohms); control windings, $N_C = 300$ turns (9 ohms); boosting windings, $N_D = 50$ turns (1.5 ohms).

Four center-tapped selenium-rectifier sets each having 2 by 4 cells with 1-inch square plates have been used, but germanium of silicon diodes may be used equally well. The resistance values of a-c bias resistors R_B, feedback resistors R_K', R_K'' and R_E', R_E'' are not critical. Thus



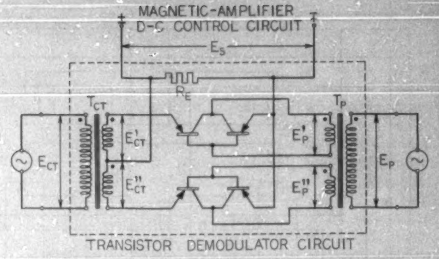


Fig. 3 (left). Star-modulator type of phase-sensitive rectifier circuit

Fig. 4 (above). Transistor demodulator circuit with auxiliary resistor, R_E

Both circuits are for the application of a polarity-reversible d-c signal voltage, E_S, to the input of the voltage-controlled self-balancing magnetic servo amplifier of Fig. 1

wire-wound or composition ("metallized") resistors may be employed in this circuit.

The graphical symbols of Fig. 1, which can be used in a general way for illustrating actual mode of operation of magnetic-amplifier circuits,[8] show that the black rectifiers are conducting simultaneously during the first half-cycle period of power-supply voltage E_P (black polarities), while the white rectifiers do conduct simultaneously during the second half-cycle period of E_P (white polarities). In this arrangement, feedback resistors, R_K', R_K'' and R_E', R_E'' in the line circuit, and motor control winding W_L', W_L'' are supplied from eight half-wave rectifier elements with variable unidirectional full-wave currents I_K', I_K'', I_E', I_E'', and I_L', I_L'' in such a way that the resultant d-c and a-c components of the four half-cycle pulses, I_1 to I_4, are polarity-reversible and are zero at zero input. Evidently, R_K' and R_K'' will carry unidirectional currents having the average values $I_K'=I_1-I_4$ and $I_K''=I_2-I_3$, whereas the motor control windings W_L', W_L'' are supplied with unidirectional currents $I_L'=I_1+I_4$ and $I_L''=I_2+I_3$, as already described in previous publications.[9-11] A common "a-c line resistor" R_T may be provided in this arrangement to limit actual magnitude of total alternating current I_T and to improve the operating conditions by reducing actual reverse voltage of the rectifier elements during the reset periods of the associated saturable-reactor elements.

In accordance with the previous graphical presentation,[11] the schematic diagrams of Fig. 2 illustrate the mode of operation of the circuit of Fig. 1 with regard to the 2-phase motor. It shows the variations of the average values of the four half-cycle pulses, I_1 to I_4, and the waveforms of the resultant motor-winding load currents I_L', I_L'', and $I_L'-I_L''$ for the typical example that, with no-signal conditions ($E_S=0$), the pulses I_1 to I_4 have 50 per cent of their maximum value, i.e., the firing angle of the four saturable-reactor elements is 90 degrees.

Evidently, with $E_S=0$, the average values of I_1 and I_4, and also those of I_2 and I_3 are equal, the fundamental-frequency components of I_L' and I_L'' are zero, and $I_L'-I_L''=0$. When a positive signal voltage, $+E_S$, is applied, the pulses I_1 and I_2 of the two "plus-minus saturable-reactor elements" will increase, while the pulses I_3 and I_4 of the two "minus-plus saturable-reactor elements" will decrease; and there is a resultant positive (0 degree) fundamental-frequency load current $I_L'-I_L''$ which is a function of the magnitude of $+E_S$. However, with negative values, $-E_S$, the pulses I_1, I_2 will decrease, the pulses I_3, I_4 will increase, and there is a resultant negative (180 degrees) fundamental-frequency load current $I_L'-I_L''$, which is a function of the magnitude of $-E_S$. Thus, the push-pull circuit of Fig. 1 will operate the separately excited 2-phase motor in the usual way by means of pure, phase-reversible alternating current $I_L'-I_L''$ (substantially without d-c component); and the feedback resistors R_K', R_K'' will produce the unidirectional, full-wave polarity-reversible negative-feedback voltage $E_K=I_K'R_K'+I_K''R_K''$ in the control-circuit loop of the amplifier. In this case, with $R_K'=R_K''=R_K$, the term $1/R_K=(I_K'+I_K'')/E_K=(I_K'+I_K'')/E_S$ represents the transconductance of the circuit with regard to the negative-feedback resistors.

Fig. 3 shows the circuit diagram of a star-modulator[12] full-wave type of phase-sensitive rectifier for converting the phase-reversible a-c error-signal voltage, $\pm E_{CT}$, of the synchro-control transformer into a polarity-reversible d-c signal voltage, $\pm E_S$. This arrangement contains the following:

1. The reference-voltage transformer T_P with ordinary core material and two center-tapped secondary windings.
2. The signal-voltage transformer T_{CT} with Supermalloy tape core and one center-tapped secondary winding.
3. Four silicon diodes.
4. Two mixing resistors R_E', R_E''.

If the reference voltages $E_1=E_2=E_3=E_4=\text{const}\times E_P$ are either in phase or 180 degrees out of phase with the signal voltages $E_A=E_B=\text{const}\times E_{CT}$ and if these reference voltages are larger than the maximum value of the signal voltages, then the polarity-reversible d-c signal voltage, $\pm E_S$, applied to the input of the test circuit of Fig. 1, will be proportional to the phase-reversible a-c error-signal voltage, $\pm E_{CT}$ of the synchro-control transformer.

In order to minimize zero-drift errors caused by large changes in power-supply voltage and ambient temperature, a transistor demodulator-circuit[13,14] may be used. In this device, Fig. 4, four p-n-p transistors having a Zener voltage of 42 volts are used as switches.[15] This type of demodulator is capable of operating at signal-voltage levels at least as low as 20 millivolts and as high as 30 volts rms with low drift over the temperature range from -65 to $+75$ degrees centigrade.[13]

When employing this transistor demodulator in connection with the d-c voltage-controlled amplifier of Fig. 1, a single auxiliary resistor R_E (Fig. 4) is provided to apply a polarity-reversible d-c control voltage, $\pm E_S$, to the input

of the amplifier. This is in contrast to the usual method, where the full polarity-reversible direct output current of the transistor demodulator flows through the control windings of the amplifier operating as a direct-current-controlled device.

Measurement of Output-Input Characteristics

Examination of the magnetic-amplifier circuit of Fig. 1 with regard to the possibility of measuring output-input characteristics makes it evident that conventional methods for making such measurements are not applicable on this arrangement and will also not be suitable in similar cases.

In order to make correct measurement of output-input characteristics on such arrangements possible, the torque-balance method was developed. It is based upon comparison of actual magnetic-amplifier output voltage with a continuously adjustable sinusoidal auxiliary voltage which has fixed phase relationship with respect to the power-supply voltage, preferably corresponding to maximum-torque operating conditions.

In accordance with the basic principle of the torque-balance method, the rotor shaft of the load motor W_PW_L has been flexibly coupled with that of an identical balancing motor W_MW_N, as shown in Fig. 5. Actual test procedure is as follows:

1. With the double-pole double-throw switch in dotted-line position, the variable substantially sinusoidal auxiliary voltage E_N is applied to the parallel-connected control windings W_L, W_N; and the variable capacitor C_M can be adjusted so that actual torque of motor system W_PW_L will be balanced by that of the opposing motor system W_MW_N. Since both torques are proportional to E_N, they will balance each other, when E_N is changed from zero up to its maximum value.

2. With the switch in solid-line position, actual highly nonsinusoidal output voltage E_L of the magnetic-amplifier output circuit is applied to control winding W_L of the load motor, whereas the variable sinusoidal voltage E_N of the balance circuit is applied to control winding W_N of the balancing motor. In this case, the torques of the two motor systems will balance each other, if E_L and E_N have equivalent effects.

3. Measurement of output-input characteristics can be achieved by varying signal voltage E_S (from zero up to its maximum value), and adjusting the variable transformer, i.e., voltage E_N so that the actual torque of system W_PW_L is balanced by the torque of system W_MW_N.

4. Graphical presentation of output-input characteristics consists then in plotting the equivalent sinusoidal output voltage E_N against signal voltage E_S, preferably with various circuit parameters.

Evidently, when following this test procedure, the torque-balance method offers the possibility of determining that value of sinusoidal voltage which produces on the 2-phase motor exactly the same torque as the actual highly nonsinusoidal output of the magnetic amplifier under test. This method which permits direct measurement of magnetic-amplifier output in terms of the equivalent sinusoidal output voltage has proved to be very practical for investigations on various full-wave and half-wave types of magnetic servo amplifiers.

Fig. 6 shows as an example a typical output-input characteristic of the circuit

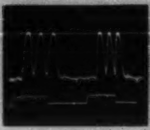

Fig. 9 (left). Half-cycle transient response of the d-c-controlled magnetic servo amplifier of Fig. 1

Lower trace indicates actual waveshape of the synchronous unidirectional square-wave signal voltage, E_S, derived from the transient analyzer of Fig. 8, and upper trace shows transient response of the full-wave negative-feedback voltage, E_K, across resistors R_K', R_K'' of Fig. 1

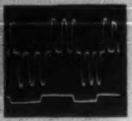

Fig. 10 (right). Half-cycle transient response of the test circuit of Fig. 1 operating as a carrier-frequency amplifier (carrier frequency f_c = 180 cycles, modulating frequency f_m = 60 cycles, frequency ratio $f_c/f_m = 3$)

Lower trace indicates waveshape of the pure a-c square-wave signal voltage derived from the transient analyzer of Fig. 8, and upper trace shows transient response of the full-wave negative-feedback voltage, E_K, across resistors R_K', R_K'' of Fig. 1

of Fig. 1. It presents the equivalent sinusoidal output voltage, i.e., the rms value of the variable sinusoidal voltage E_N, indicated by the iron-vane voltmeter, as a function of the polarity-reversible d-c signal voltage E_S with feedback resistance $R_K = R_K' = R_K''$ as a parameter.

The effective input resistance of the control circuit is dependent on the actual magnitude of control-winding current I_C (Fig. 1). Therefore, application of Supermalloy tape cores may be preferred in some cases to minimize actual magnetizing-current requirements of the control circuit. Since this amplifier does not contain any rectifier components in its control circuit, the control magnetizing current is capable of assuming any magnitude and direction necessary to support the actual magnetic-flux conditions imposed by the applied voltages. As a result of this very important fact, the amplifier will maintain its unique features even when employing substantially nonremanent core materials; and even lower-grade core materials may successfully be used in some cases.

Average value of control-winding current I_C has been measured by means of a shunted mirror-type galvanometer. Fig. 7 shows I_C as a function of polarity-reversible d-c signal voltage, $\pm E_S$, when a properly rated regeneration-control resistor R_D is provided in the differential-boosting circuit N_D', N_D''; R_D', R_E'', R_R (using "critical regeneration" conditions[3]) Evidently, average value of I_C varies within the limits of from 0 to ±100 microamperes, and the a-c component of I_C may be reduced to values of the same order by introducing a choke coil into the control circuit[16] without affecting the half-cycle response of the amplifier.

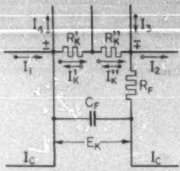

Fig. 11. Application of frequency-sensitive components (integrating circuit C_FR_F) in the degeneration network of the magnetic servo amplifier of Fig. 1, which permits elimination of the tachometer generator, as conventionally used for stabilization of closed-loop servo systems

Measurement of the Transient-Response Time

For servo applications, a high speed of response of the amplifier is of paramount importance. Application of the fundamental principle of the single-stage self-balancing magnetic amplifier, i.e., combination of positive magnetic feedback and negative electric feedback,[3] offers the possibility of reducing actual response time of the amplifier to its minimum value of 1 half-cycle of the power-supply frequency by introducing 100-per-cent negative feedback[16,17] without employing any rectifier components in the control circuit of the amplifier.

Analysis of the self-balancing magnetic-amplifier circuit of Fig. 1 reveals that half-cycle response will be obtained if turns ratio N_C/N_A (total) is approximately equal to the resistance ratio R_K/R_O, where $R_K = R_K' = R_K''$ is the actual resistance of the negative-feedback resistors, and R_O is the total resistance of each output-circuit component including the load-resistance elements, copper resistance of the gate windings N_A, and forward resistance of the rectifier units.

Referring to the use of the regeneration-control circuit, it is to be noted that this circuit, when improperly rated, i.e., if the ratio N_D^2/R_D is too large, will produce an appreciable additional time delay in the transient response of the amplifier. If N_D^2/R_D is too large, then this circuit—in a similar way as the control-circuit ratio N_c^2/R_c of a conventional full-wave magnetic-amplifier circuit—will produce an excessive additional time delay (in the order of 1 or 2 cycles of the power-supply frequency); and, in this case, the typical half-cycle response of this amplifier will be lost. For this reason, separate positive-feedback resistors R_E', R_E'' are provided which make it possible to bring the ratio $N_D^2/(R_D + R_E' + R_E'')$ to a sufficiently small value and to preserve half-cycle response of the amplifier.

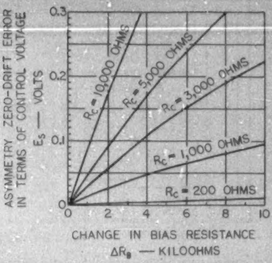

Fig. 12. Measured values of the asymmetry zero-drift error expressed in terms of d-c signal voltage, E_B, as a function of bias-resistor variation, ΔR_B, with the control-circuit resistance, R_C, as a parameter

A simple method for experimental studies on the dynamic properties of high-speed magnetic amplifiers consists in applying a synchronous square-wave signal voltage E_S derived from a motor-operated transient analyzer.[1] This device, which is operated by means of a mechanical switch, does permit direct visual observation of a stationary pattern. However, as already pointed out, application of this device is limited to low power-supply frequencies where a mechanical switch can be operated in a reliable way. For this reason, a novel type of synchronously operated transient analyzer was developed which may be used equally well in the range of higher power-supply frequencies, for example, those derived from magnetic frequency multipliers.[2]

The transient response of the circuit of Fig. 1 has been studied by connecting the amplifier with the 180-cycle output of a 60/180-cycle 3-phase type of magnetic frequency tripler (consisting of three saturable reactors SR, and three linear reactors LR).[2] The input of this tripler is supplied from the 60-cycle power supply which also feeds a phase shifter and a 2-core saturable-reactor circuit acting as a magnetic switch (Fig. 8).

The fundamental principle of this arrangement is based upon the fact that the actual wave shape of the alternating (load) current I_M of an ordinary saturable reactor with rectangular-hysteresis-loop core material (a transductor having series-aiding-connected a-c load windings N_M', N_M'' and series-opposing-connected d-c control windings N_C', N_C'') is nearly rectangular, if the control-circuit loop carrying constant direct current I_C represents a very high impedance (choke coil L_C) with regard to even-harmonic currents.[18–20] In this case, these even-harmonic currents are suppressed, and the saturable-reactor circuit does operate under forced-magnetization conditions.[21] In order to derive corresponding unidirectional square-wave pulses (signal voltage E_S) from the square-wave alternating current I_M, a splitting circuit[22] is provided. It consists of two half-wave rectifiers D_M', D_M'', with potentiometer resistor R_M' ("black" first-half-cycle pulses I_M') and fixed resistor R_M'' ("white" second-half-cycle pulses I_M'').

The oscillogram of Fig. 9 shows the transient response of the circuit of Fig. 1. It has been obtained by applying the synchronous square-wave signal voltage, E_S, derived from the magnetic-switch circuit of Fig. 8. The lower trace of Fig. 9 indicates this signal voltage, and the upper trace shows the transient response of the full-wave negative-feedback voltage E_K across resistors R_K', R_K''. Evidently, the response time is 1 half-cycle of the power-supply frequency, i.e., with $f_P=$ 400 cycles, the amplifier does reach 100 per cent of its final steady-state output current 1.25 milliseconds after the transient signal voltage E_S is applied; and the output current drops to zero 1.25 milliseconds after E_S is suddenly removed.

When employing the arrangement of Fig. 1 in connection with a 60/180-cycle or 400/1,200-cycle magnetic frequency tripler (without using a phase-sensitive rectifier in the control circuit) in a carrier-frequency system,[2] the line-field winding W_P of the motor will be separately excited in the usual way by a 60-cycle or 400-cycle current I_P. The motor control-winding components W_L', W_L'', however, will be introduced into the circuit of Fig. 1 in such a way that the pulses I_1, I_2 from the "plus-minus saturable-reactor elements" will flow through winding W_L', while the pulses I_3, I_4 from the "minus-plus saturable-reactor elements" flow through winding W_L''. In this case, the self-balancing half-cycle-response magnetic servo amplifier operates as a real a-c amplifier with a frequency-multiplier carrier frequency $f_c=180$ or 1,200 cycles a modulating error-signal frequency $f_m=$ 60 or 400 cps, and the frequency ratio $f_c/f_m=3$.

The oscillogram of Fig. 10 concerning this mode of operation has been obtained by applying the alternating voltage drop across the splitting circuit of the magnetic-switch arrangement, i.e., a pure alternating 60-cycle square-wave signal voltage, to the input of the circuit of Fig. 1. The lower trace of Fig. 10 indicates this signal voltage, and the upper trace shows the typical half-cycle transient response of the negative-feedback voltage, E_K, across resistors R_K', R_K'' corresponding to actual transient respose of the polarity-reversible output of the amplifier.

Measurement of Bandwidth on a 400-Cycle Closed-Loop System

Dynamic performance of the single-stage amplifier of Fig. 1 has been investigated by operating this amplifier in connection with a standard-type 400-cycle position servomechanism and the star-modulator[12] full-wave phase-sensitive rectifier of Fig. 3.

The half-cycle transient response of the arrangement of Fig. 1 does reduce the stabilization problems that usually accompany use of magnetic amplifiers in closed-loop servo systems. Measurement of bandwidth on a 400-cycle position servomechanism using a "servoscope" has shown that the bandwidth is about 17 cycles (107 radians), when a tachometer generator is employed in the usual way for stabilizing the servo system.[23] Bandwidth values of the same order have been obtained, when eliminating the tachometer generator by introducing frequency sensitive components[24] (e.g., the integrating circuit C_FR_F of Fig. 11) into the negative-feedback channel of the amplifier.

Measurements Concerning Reduction of Asymmetry Zero-Drift Errors

In order to illustrate the significant effect of drift-error reduction in self-balancing magnetic amplifiers, actual value of the asymmetry zero-drift error, expressed in terms of d-c signal voltage E_S has been measured: (1) without making any change in circuit configuration of Fig. 1; (2) providing the same voltage gain of the amplifier in all cases; (3) with various total-resistance values (R_C) of the control circuit; and (4) with various amounts of asymmetry. Well-defined amounts of asymmetry of the test circuit, Fig. 1, have been introduced by varying only one bias resistor (R_B) within the limits of from 30 to 40 kilohms, while the other three bias resistors (30 kilohms) remained unchanged.

Fig. 12 presents the measured values of asymmetry zero-drift error expressed in terms of d-c signal voltage E_S as a function of bias-resistor variation ΔR_B with the control-circuit resistance R_C as a parameter. The results of these measurements, Fig. 12, show in a dramatic way that, when reducing the total control-circuit resistance from the conventional value of 10,000 ohms to about 100 to 200 ohms and applying self-balancing operating conditions with critical regeneration (the effective input resistance E_S/I_C is at least 10,000 ohms), the actual magnitude of the asymmetry zero-drift error is reduced to about 1/40 of its original value. This is, of course, also true when the asymmetry of the push-pull circuit is caused by other effects, e.g., variations of the characteristics of the saturable-reactor and rectifier components. Thus, because the requirements on grading and matching of these components are greatly reduced, the single-stage self-balancing type of magnetic servo amplifier, Fig. 1, lends itself admirably to quantity-production techniques.

Finally, it is important to stress the fact that the drastic reduction of asymmetry zero-drift errors (Fig. 12) in the self-balancing magnetic-amplifier circuit of Fig. 1 is the result of combination of the dynamic gain-increasing effect of magnetic positive feedback and the drift-reducing effect of electric (galvanic) feedback, resistance-coupled into the control-circuit loop.[3,4] With regard to the great importance of this basic concept, H. F. Storm[26] has pointed out that "if one is confronted with the choice of either increasing the control-circuit resistance or applying negative electric feedback, it is well to remember that an increase of control-circuit resistance cannot change the drift, but an equivalent application of negative electric feedback will reduce the drift."

High-Temperature Selenium Rectifiers—A Survey of Manufacturers' Data

T. S. SHILLIDAY
NONMEMBER AIEE

ABOUT a year ago the Subcommittee on Technical Information of the AIEE Metallic Rectifier Committee undertook a program for the purpose of accumulating information on high-temperature selenium rectifiers. As one part of that program Battelle Memorial Institute acting in behalf of the Metallic Rectifier Committee prepared and sent to selenium rectifier manufacturers a questionnaire on high-temperature selenium rectifiers. The 85-per-cent response to the questionnaire is an indication of the fine co-operation extended by the manufacturers. The information thus obtained was used to assemble a report to the sponsoring committee. That report, supplemented by additional information obtained through personal contacts with a few manufacturers, make up the contents of this paper. To avoid possible disclosure of proprietary information, the discussion will be kept on a general level. It is hoped, however, that a survey of the views, achievements, and direction of a major portion of the industry will be found of some value to both the manufacturer and the consumer.

Discussion of Rectifier Ratings

Each of the ten organizations from which a reply was received manufactures rectifiers for operation in ambient temperatures in excess of 50 C. Of these rectifiers, some are specially designed high-temperature cells and some are standard cells capable of high-temperature operation for limited periods with proper derating.

Data were submitted in a number of ways and in varying detail. Graphical means have been used to reduce some of these data to a common base. Relationships between expected life, rating, and ambient temperature are presented in the first four figures. Standard and high-temperature rectifiers have been treated separately to make clear the differences between them. In these figures, normal rating refers to a forward current density approximately equal to the National Electrical Manufacturers Association (NEMA) standard of 320 milliamperes per inch^2 for a single-phase bridge. Likewise, voltage per cell is, in most cases, 26 volts. Exceptions will be noted as they occur.

Fig. 1 shows current rating as a function of ambient temperature for standard rectifiers marketed by seven different manufacturers. Each symbol represents a different manufacturer. The table at the top of the graph lists the available information on expected life for each rectifier under various combinations of current rating and ambient temperature.

It will be noted that expected life at 50 C and lower ranges from 10,000 hours up for all rectifiers. At temperatures above 50 C, and for rectifiers falling within the area enclosed by dashed lines, reported life ranges from 1,000 to 3,000 hours. This area has been chosen rather arbitrarily to include the temperatures and ratings at which rectifier life is limited. With one exception, those rectifiers falling below the enclosed area have expected lives of 10,000 hours or greater. This increased life is presumably the result of more severe derating, and it is expected that lives of the order of 1,000 to 2,000 hours might be exhibited by these rectifiers at the higher ratings.

Fig. 2 shows voltage rating as percentage of normal rating at different ambient temperatures for the same rectifiers. A given manufacturer is represented by same symbol here as in Fig. 1. It can be seen here that voltage is not derated below 50 C and that usually, voltage derating is less severe than current derating.

Paper 56-77, recommended by the AIEE Metallic Rectifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 20, 1955; made available for printing December 12, 1955.

T. S. Shilliday is with the Battelle Memorial Institute, Columbus, Ohio.

Grateful acknowledgment is made of the contributions to the subject matter of this paper by the following companies: Bradley Laboratories; Fansteel Metallurgical Corporation; Federal Telephone and Radio Company; General Electric Company; P. R. Mallory and Company; Radio Receptor Company; Sarkes Tarzian Inc.; Union Switch and Signal Company; Vickers Electric Division of Vickers, Inc.; and Westinghouse Electric Corporation. With one exception each of these organizations manufactures, in commercial quantities, selenium rectifiers for operation in ambient temperatures at 125 to 150 degrees centigrade (C).

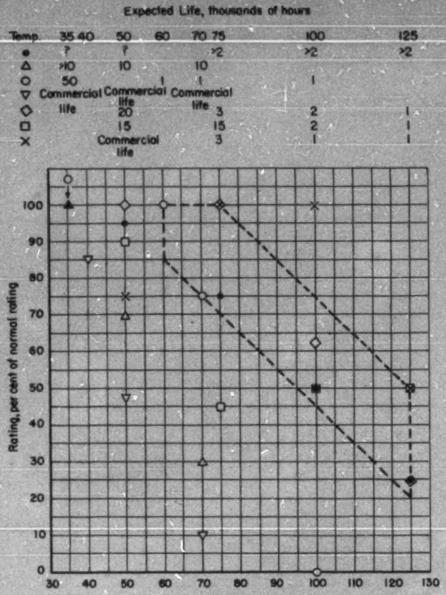

Fig. 1. Current derating and expected life for standard rectifiers at various ambient temperatures

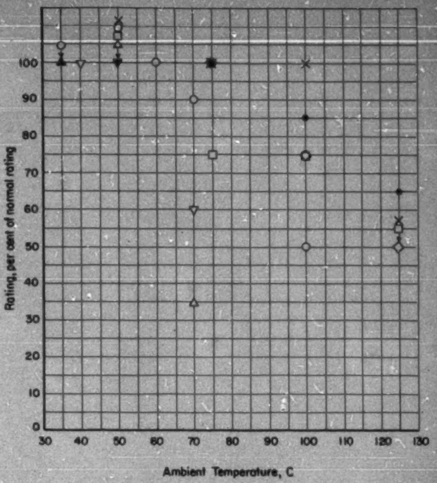

Fig. 2. Voltage derating for standard rectifiers at various ambient temperatures

It should be pointed out that the scatter in points on these two graphs and those to follow is not due entirely to product nonuniformity between manufacturers. This problem deals with four variables, current and voltage rating, ambient temperature, and expected life, none of which is independent of the others. With data coming from several sources it was inevitable that differences in manner of presentation would occur. Those data have been used here essentially as received. However, study of the graphs will show that some interpolation may be possible.

Of this group of seven manufacturers, those represented by the dot, the triangle, and the inverted triangle produce other selenium rectifiers specifically designed for operation at elevated temperatures. The manufacturers represented by the dot and inverted triangle reported that voltage ratings up to 40 volts per cell are available.

Fig. 3 shows the relationship between current rating, ambient temperature, and expected life for selenium rectifier cells designed for high-temperature operation. A given manufacturer is, in general, not represented by the same symbol in these high-temperature rectifier data as in the standard rectifier data.

In this graph the rectifier represented by the inverted triangle is a 24-volt cell, the one represented by the circle is a 45-volt cell, and the one represented by the square is available in 26- and 33-volt ratings. It will be noted that with two exceptions (the dot and the circle) the indicated life of high temperature rectifiers in ambient temperatures above 75 C is not significantly greater than that of standard rectifiers in the same temperature range. However, output current derating is generally much less severe and in two cases operation is extended to 150 C. The enclosed area from Fig. 1 has been superimposed on this graph to facilitate a comparison of the range of current ratings.

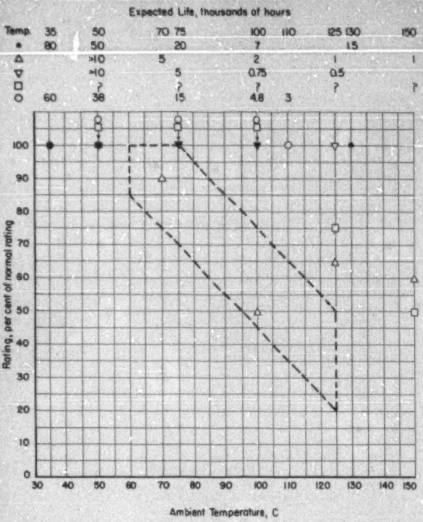
As shown in Fig. 4, only one of the manufacturers under discussion derates the input voltage of his high-temperature rectifier. This manufacturer has pointed out that his high-temperature rectifier is a rather new development and that until more extensive tests have been completed, the ratings on it are tentative and probably conservative.

An attempt was made to estimate rough averages of the current rating data available for standard and high-temperature rectifiers, taking into account expected cell life. The result is shown in Fig. 5. While these curves are not meaningful for the data of any given manufacturer, they do indicate the generally superior capabilities of rectifier cells designed for high-temperature operation.

Nearing completion in several laboratories are developments which should make available selenium rectifiers capable of several thousand hours operation at 125 C without derating. It is expected that plates such as these will operate without derating for 5,000 hours at 125 C. Life and rating at 150 C are as yet undetermined definitely but look very promising. One manufacturer reports a maximum ambient operating temperature somewhere between 150 and 200 C.

Factors Influencing Rectifier Aging

There was general agreement among manufacturers regarding the influence of output current density, input voltage, and ambient temperature on rectifier aging. An increase in any one of these factors accelerates aging; decreases in them reduce the rate of aging. Load current and cell temperature are the most important factors. Sufficient data are not available from the survey to define



Expected Life, thousands of hours

▽		>10		5	0.75		0.5		
□		?		?	?		?		?
○	60	38		15	4.8	3			

Fig. 3. Current derating and expected life for high-temperature rectifiers at various ambient temperatures

clearly the extent of influence of input voltage on aging.

In discussing the relative effect of temperature and current density on rectifier aging one contributor reported that his test data suggested an approximately straight-line relationship between current density and forward aging rate in the range of cell temperature of 60 to 80 C. To the aging caused by current, this manufacturer adds the aging caused by cell temperature. It was pointed out that the effects of these two aging phenomena are approximately equal at 60 C. At 80-C cell temperature, the effect of temperature is greater than that of current density and at still higher temperatures the proportionate effect of temperature becomes still greater. Another manufacturer places this critical temperature at 100 C, at which cell temperature starts to become more important than current density for his rectifier.

A third contributor suggests that internal temperature rather than cell temperature (in the sense of plate surface temperature) may be a more meaningful parameter in the aging phenomenon. For a fixed cell or surface temperature, changes in current density alter the temperature gradient in the plate. Therefore, the same surface temperature at different current densities may not necessarily indicate the same internal temperature. Good aging characteristics have been obtained on cells operated at excessive current densities when clamped between large water-cooled blocks of copper, suggesting that internal temperature gradient is the critical factor.

It is believed that these two viewpoints are compatible since, if cell surface temperature is permitted to increase beyond the critical point at a given current density, the internal temperature gradient in the cell may be reduced or the rate of dissipation of thermal losses in the cell may be reduced.

Detailed comparison of the characteristics of standard and high-temperature cells at a given temperature were not obtained. However, three of those reporting stated that forward voltage drop

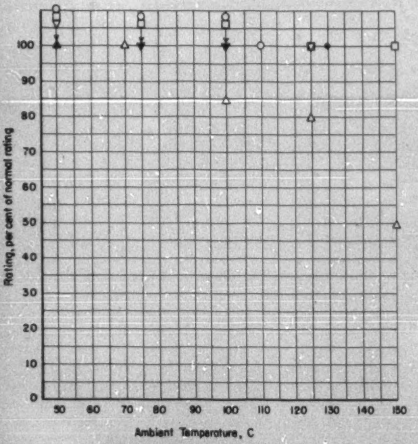

Fig. 4. Voltage derating for high-temperature rectifiers at various ambient temperatures

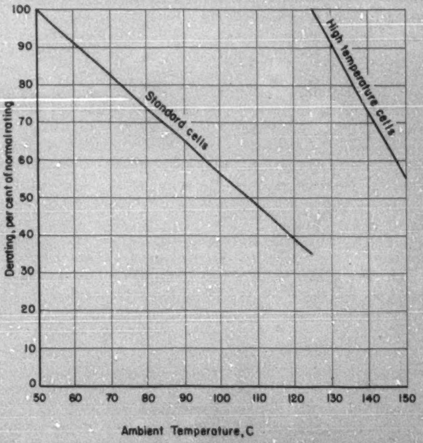

Fig. 5. Average current rating as a function of ambient temperature based on data available on standard and high-temperature selenium rectifiers

in their high-temperature cells at room temperature were 5, 10, and 60 per cent higher than their respective standard cells. This higher voltage drop, of course, decreases as ambient cell temperature is increased, because of the negative temperature coefficient of forward resistance.

Leakage currents of high-temperature cells in some cases change little or decrease slightly as ambient temperature increases. One manufacturer reported that compared to standard cells, his high-temperature cells exhibit very little unforming during storage. In these rectifiers the barrier layer is more stable and less affected by temperature and humidity.

Methods for Protection from Environment

Several methods are in use for protecting selenium rectifiers from contamination by ambient atmospheres. Depending on the application, industrial units are hermetically sealed, sealed in nylon enclosures, encapsulated in oil, embedded in a resin, or dipped or sprayed with a phenolic or vinyl-base enamel. The most widely reported protection from humidity or salt spray consists of a chlorinated rubber paint. One company uses a double coat of pigmented Bakelite varnish for protection from humidity, salt spray, or acid atmospheres. When protection from fungus is required, fungicidal varnishes are applied over other protective layers.

In evaluating the quality of a protective coating prior to its use in production the stated practices consist in general of:

1. Checking the compatibility of the finish and its solvent with the rectifier by an extended immersion test followed by electrical measurements on the rectifier. Where two types of paint must be used, their compatibility with each other is also checked.
2. Investigating the temperature characteristics of the protective coating by subjecting sample stacks to cyclic changes in ambient temperature, followed by examination of the electrical properties of the rectifier and the physical condition of the coating.
3. Studying the physical and electrical effect of humidity and salt spray on the rectifier and the coating.
4. Extensive life testing of rectifiers protected with the coatings passing the foregoing tests.

Summary

To summarize, four of the reporting manufacturers derate their standard rectifiers to permit operation at 125 C for periods up to 1,000 hours. Six manufacturers produce high-temperature rectifiers for operation at 125, 130, or 150 C. The expected life reported for the high-temperature cells is not significantly longer than that for standard cells at equivalent temperatures. However, high-temperature types do operate at much higher current and voltage ratings at elevated temperatures. It is also possible to rate cells at higher than NEMA ratings when used in short stacks or with wide spacing. Ratings exceeding the NEMA standard are also achieved by accepting reduced life expectancy, lower ambient operating temperature, or both.

The expected rectifier life figures cited in this paper are based on a 75- or 100-per-cent increase in forward voltage drop or a 10-per-cent decrease in output voltage. In many actual service applications, a much greater degree of aging may be permissible with correspondingly longer life. It is believed therefore that the ratings and life presented in this paper should be considered conservative.

Throughout the industry, research and development are being directed to many facets of selenium rectifier improvement. The high-temperature selenium rectifier is a major subject of these investigations. It appears at present that rectifiers capable of several thousand hours' operation without derating in a 125 C ambient will be available in the near future. Operation has already been extended to 150 C but much further improvement in performance at this temperature may be expected in the years to come. Because high-temperature cells are being designed for operation without derating at elevated temperatures, improved performance at normal temperatures should also be realized. Examples of this improvement are observed in Fig. 3 where 80,000 and 60,000 hours of useful life are reported for 26- and 45-volt high-temperature cells respectively.

◆

Discussion

J. Gramels (Bell Telephone Laboratories, Inc., New York, N. Y.): The author's survey on life expectancies and derating factors for high-temperature operation of selenium rectifiers is of great interest to the design and application engineer of power supplies. The data are a valuable guide to the engineer who is responsible for equipment that must meet a specified minimum number of hours of operation, particularly in military projects where higher ambient temperatures in the equipment are encountered because of confined space limitations.

It is also evident that there are considerable differences in manufacturers' derating factors and expected life. In this connection it may be interesting to report some studies made at the Bell Telephone Laboratories on selenium stacks operated at an 80 C ambient temperature.

This temperature was selected because it was somewhat in excess of the conventionally accepted theory that if selenium rectifiers were operated at cell temperatures above 75 C, a drastic reduction in life may be anticipated. The tests were conducted on the standard 26-volt type of selenium cells and are not to be confused with the more modern type of "high-temperature" cells.

The cells were operated at full-rated load current (320 milliamperes per square inch, single-phase full-wave circuit rating, NEMA standards). The a-c input voltage, however, was derated to 80 per cent of the maximum rating. Periodically, tests were made of the increase in the forward voltage drop at the rated current. As shown in Fig. 6, the data were plotted as per-cent increase from the initial forward drop. A 100-per-cent increase in this drop was chosen at the end of life (NEMA standards specify 75 per cent).

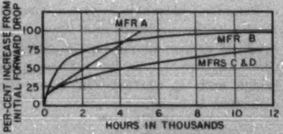

Fig. 6. Selenium rectifiers operated at +80 C ambient. Cells rated at 26 volts. Constant input voltage, 80-per-cent normal rating. Resistance load, 100-per-cent load current rating. Forward aging (a-c short-circuit test at rated current). Standard cells not processed for high-temperature operation. Data taken at room temperature

These results, as pointed out by the author, indicate a wide variation of life expectancy on different manufacturers' products. It also shows the difference in the rates of aging. The aging rate on stacks made by manufacturer *A* is essentially a linear function, indicating a life of about 5,000 hours. Stacks from manufacturers *B*, *C* and *D* exhibit an accelerated aging rate for the first few thousand hours, and then the aging rate tapers off for the duration of the test. The stacks from manufacturer *B* show an expected life of 12,000 hours, while stacks from manufacturers *C* and *D* have a life expectancy greater than 12,000 hours.

Cell temperature measurements under 80 C ambient temperature operation were not taken, but it is estimated that these temperatures were approximately 100 C.

Considering that: 1. These data were obtained on standard-type cells, not on high-temperature cells, and 2. The stacks were operated without current derating factors usually recommended at elevated temperature operation, the life expectancy obtained in these studies exceeded our expectations.

T. S. Shilliday: The information on which the paper is based consists, in general, of manufacturers' published rating data. Such data are believed by the author to be on the conservative side in most instances. Unfortunately, circumstances did not permit the performance of life tests at Battelle on representative samples of each manufacturer's rectifier. The value of such tests, however, in comparing the ultimate performance of rectifiers from various sources is clearly indicated by the curves presented by Mr. Gramels.

The "standard" rectifiers of the type upon which Mr. Gramel's data are based are covered in Figs. 1 and 2. A comparison of these data will show that the life of manufacturer *A*'s rectifier is reasonably typical of that which might be expected from the rectifiers represented by the diamond and the cross under similar operating conditions. However, the performance of the rectifiers of manufacturers *B*, *C*, and *D* far surpasses that predicted by data used in the survey.

The results of this comparison corroborate the opinion that published rating data are generally conservative, and point up the value of test data to supplement rating information for specified conditions, providing the test data are obtained from representative samplings.

The Use of an A-C Bridge to Measure Core Loss at High Inductions

I. L. COOTER
MEMBER AIEE

W. P. HARRIS
NONMEMBER AIEE

A KNOWLEDGE of the total core loss and its components is of vital importance to design engineers who use ferromagnetic materials which are subject to magnetic flux changes in direction or magnitude. Generally this information is obtained from measurements made on strip samples in an Epstein frame, with the use of a wattmeter. In many cases, however, there would be certain advantages, such as increased sensitivity and greater frequency range, in making these loss measurements by a bridge method. For measurements at low inductions and high frequencies the bridge methods have been successfully used for several years.[1,2] However, if the induction is increased over 10 to 12 kilogausses in nonoriented silicon steels or 16 to 18 kilogausses in oriented silicon steels, the distortion in the wave form of the exciting current is considerable, and it has been found that the results obtained with the bridge methods hitherto used differ from those obtained with the wattmeter. This difference increases rapidly with increases in induction. The bridge method always indicates larger power losses.

The discrepancies between results obtained at high induction by the two methods have generally been recognized as being caused by harmonic components in the exciting currents which result from the nonlinear element (iron-cored coil) in the circuit. Peterson[3] analyzed the problem of measuring the impedance of a nonlinear circuit element and suggested an approach to the solution of the problem. He assumed that the nonlinear element was equivalent to passive elements of resistance and inductance and a series of generators of harmonic frequencies. The element absorbs energy at fundamental frequency and delivers energy to the circuit at harmonic frequencies. The energy dissipated in the element will be the difference. This approach has been experimentally investigated[4,5] but with only partial success. This paper describes a more comprehensive application of Peterson's harmonic generator concept to the bridge problem, and shows that excellent agreement may be obtained in core loss measurements between the bridge and wattmeter even when the distortion is high.

Wattmeter Method

The most generally accepted way of measuring total core loss in sheet material at power frequencies is by the wattmeter method as specified by the American Society for Testing Materials.[1] The 25-centimeter (cm) Epstein test requires flat-rolled material cut into strips 3 cm wide and 28 to 30 cm long. The strips are assembled in the four arms of the test frame with double-lap joints at the corners. The diagram of connections for the core loss test is shown in Fig. 1.

W is the wattmeter the current coil of which is connected in series with the primary winding of the test frame. The voltage coil is connected to the secondary winding of the test frame. The average-indicating voltmeter is used 1. for determining the maximum induction in the specimen in accordance with Camilli's method,[6] and 2. in conjunction with the rms-indicating voltmeter for calculating the form factor of the secondary voltage.

Bridge Method

The bridge method consists essentially in measuring the resistive component of the impedance of the coil containing the test specimen, and the exciting current. From these values and the ohmic resistance of the coil, the power loss is computed. If R_d is the apparent increase in the resistance of the coil due to the core loss in the specimen and I is the current in the winding, the power loss is taken to be I^2R_d. This simple calculation is valid, however, only if the effect of harmonic components in the exciting current is so small that it can be disregarded. This condition obtains only at very low inductions.

Several different types of bridge[1] have been used for measuring core loss. In the present investigation, however, attention was confined to the Maxwell-Wien circuit illustrated in Fig. 2.

R_a and R_c = bridge product arms
R_{dt} and L_d = measured values of resistance and inductance of the self inductor
R_b and C_b = balancing resistance and capacitance
R_s = resistance of the source

Paper 56-26, recommended by the AIEE Instruments and Measurements Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 19, 1955; made available for printing November 10, 1955.

I. L. COOTER and W. P. HARRIS are with the National Bureau of Standards, Washington, D. C.

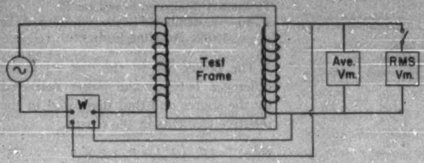

Fig. 1 (above). Connections for core loss test using wattmeter

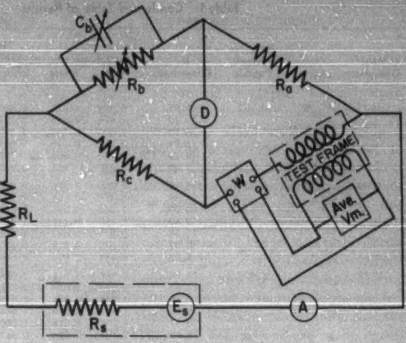

Fig. 3 (right). Comparison circuit for measuring core loss with wattmeter and bridge simultaneously

R_L = resistance of the leads, contacts, meters, etc.

D = tuned detector, sensitive only to the fundamental frequency in ordinary bridge measurements

The balance equations are

$$R_{dt} = \frac{R_a R_c}{R_b}$$

$$L_d = C_b R_a R_c$$

Simultaneous Measurements with Bridge and Wattmeyer

To compare directly the results obtained by the bridge with those obtained with a wattmeter, the circuit shown in Fig. 3 was used. A mutual inductance was used to compensate the air flux, but is not shown. A simplified diagram showing the various components involved is given in Fig. 4. It can be seen that the current coil of the wattmeter is simply inserted in the bridge arm containing the Epstein frame. Thus, by energizing the potential coil of the wattmeter from the secondary winding of the test frame, simultaneous measurements can be made by the two different methods. The wattmeter was a sensitive light-beam electrodynamic instrument which had been calibrated at power factors down to zero and frequencies up to 300 cycles per second. The results obtained with the wattmeter were taken as the standard values with which to compare the results obtained by the bridge.

The circuit is equivalent to Fig. 4, where

R_{wm} = resistance of the wattmeter

R_w = resistance of the primary windings of the frame and compensating mutual inductance

R_d = excess of the apparent resistance of the test winding over its ohmic resistance

R_{dt} = observed resistance

L_d = apparent inductance of that arm of the bridge

When the bridge is balanced

$$R_{dt} = \frac{R_a R_c}{R_b}$$

where $R_{dt} = R_{wm} + R_w + R_d$. From this, $R_d = R_{dt} - R_{wm} - R_w$.

If, in the bridge circuit shown in Fig. 4, the sum of R_a and R_b is made so much greater than the sum of the resistance of the other arms of the bridge that the power loss in the arms containing R_a and R_b is negligible with respect to the total this part of the circuit may be disregarded in the calculation.

The power delivered by the source is

$$P_s = \sum_{1}^{k} I_h^2 (R_d + R_w + R_{wm} + R_c + R_s) \qquad (1)$$

where $R_s = R_L + R_s$ and I_h = harmonic current in the circuit due to the electromotive force of the source E_h. Also

$$P_s = \sum_{1}^{k} E_h I_h \cos \theta_h \qquad (2)$$

*American Iron and Steel Institute.

These data are not corrected for instrument loss or form factor.

where θ_h is the angle by which the harmonic component of current I_h lags the harmonic component of voltage E_h.

If the voltage generated by the source contains no harmonics of significant magnitude, only the voltage of fundamental frequency needs to be considered, and

$$P_s = I_1{}^2R_d + I_1{}^2R_p \tag{3}$$

where $R_p = R_w + R_{wm} + R_c + R_e$

Also

$$P_s = E_1I_1 \cos \theta_1 \tag{4}$$

Let

P_d = power loss in the core

P_{wm} = power dissipated in current coil of wattmeter

P_w = power dissipated in the winding of the test frame due to its ohmic resistance

P_c = power dissipated in resistor R_c

P_e = power dissipated in the resistance of the source including leads, etc.

The power loss in the iron P_d is the difference between the power delivered by the source and that dissipated in the resistive elements in the circuit.

$$P_d = P_s - (P_w + P_{wm} + P_c + P_e) \tag{5}$$

Although the voltage of the power source is known to be practically free of harmonics, the current may contain large harmonic components when the circuit contains a nonlinear element. Then

$$P_w + P_{wm} + P_c + P_e = \sum_1^k I_h{}^2(R_w + R_{wm} + R_c + R_e)$$

and from equation 4 $P_s = E_1I_1 \cos \theta_1$. The result is

$$P_d = E_1I_1 \cos \theta_1 - \sum_1^k I_h{}^2(R_w + R_{wm} + R_c + R_e) \tag{6}$$

Since only odd harmonics can be produced in the circuit by the iron-cored coil, then

$$\sum_1^k I_h = I_1 + I_3 + I_5 + I_7 + \ldots + I_k$$

$$\sum_1^k I_h{}^2(R_w + R_{wm} + R_c + R_e) = \sum_1^k I_h{}^2R_p = I_1{}^2R_p + \sum_3^k I_h{}^2R_p$$

Then

$$P_d = E_1I_1 \cos \theta_1 - I_1{}^2R_p - \sum_3^k I_h{}^2R_p$$

From equations 3 and 4

$$E_1I_1 \cos \theta_1 = I_1{}^2R_d + I_1{}^2R_p \tag{7}$$

$$P_d = I_1{}^2R_d + I_1{}^2R_p - I_1{}^2R_p - \sum_3^k I_h{}^2R_p$$

$$P_d = I_1{}^2R_d - \sum_3^k I_h{}^2R_p \tag{8}$$

Equation 8 shows quantitatively the relationship indicated in the foregoing, i.e., the true power P_d dissipated in the iron of the iron-cored coil is the total power supplied to the iron at fundamental frequency minus the power dissipated in the circuit at harmonic frequency. The harmonic power term

$$\sum_3^k I_h{}^2R_p$$

can be considered as being supplied by harmonic generators in the iron.

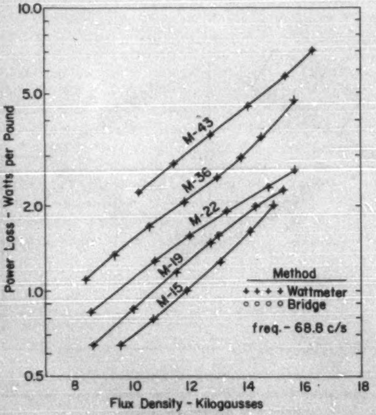

Fig. 5. Comparison of results obtained by the wattmeter and bridge for several grades of material

It should be noted that equation 8 is derived on the basis that R_p is independent of frequency. At power frequencies this assumption is permissible in so far as R_w, R_{wm}, R_e and R_L are concerned, but may not always be correct in the case of R_s. A more accurate equation is

$$P_d = I_1^2 R_d - \sum_3^k I_h^2 (R_w + R_{wm} + R_e + R_L) - \sum_3^k I_h^2 (R_s)_h \quad (9)$$

For the power source used in this investigation, however, R_s was found to be practically independent of frequency so that equation 8 will give valid results.

A wattmeter properly connected to the iron-cored coil will read the correct power dissipated in the core since it is an integrating device, and will automatically perform the operation of subtracting the power delivered by the coil at harmonic frequency, from the power supplied to the coil at fundamental frequency. However, any power measuring device which measures power at fundamental frequency only, will read the input power.

The power is supplied to the circuit by a source consisting of an oscillator having low distortion and a 200-watt power amplifier. This source was found to have a voltage wave form with a total distortion of less than 0.2 per cent (%) when delivering a current of 2 amperes to a resistive load. When connected to the bridge circuit, the apparent voltage distortion did not exceed 1.3% even though the current distortion was more than 50% in some cases. This increase in apparent distortion in the voltage wave is attributed to the $I_h R_s$ drop.

This circuit has several distinct advantages for the study of bridge measurements. The total resistance is low so that the voltage of the power source does not have to be high or the power dissipation very great in order to obtain sufficient current in the test frame to approach saturation induction. Measurements can be made on the sample using the wattmeter and bridge simultaneously. These measurements are made with the same flux density in the sample and with the same exciting current having identical harmonic components and wave form. Furthermore, the form factor and instrument loss corrections are the same for both methods and, for purposes of comparing the two methods, they need not be applied. The circuit therefore permits a direct comparison of the two methods under identical conditions of measurement and without requiring the application of the usual corrections.

Observations and Results

A 25-cm Epstein frame was used in the measurements of core loss for this investigation. It was built according to the specification of the American Society for Testing Materials with a total of 700 turns in the primary winding and 700 turns in the secondary winding. An inductor was used to compensate for air flux.

The specimens used in the frame were 3 cm wide and 28 cm long; the weight of each sample was approximately 500 grams. Five types of material were used with the following designations:

AISI* Designation	Grade	Approximate Silicon Content
M-15	transformer	3.5% to 5%
M-19	transformer	3.5% to 5%
M-22	dynamo	2% to 3.5%
M-36	electrical	0.5% to 2%
M-43	armature	0.5% to 2%

* American Iron and Steel Institute

Samples of these materials were inserted in the 25-cm Epstein frame using double-lapped joints. The primary or magnetizing winding of the test frame was connected in series with the primary winding of a compensating mutual inductor and the current coil of the electrodynamic wattmeter. Together these formed one arm of the Maxwell-Wien bridge for which the simplified diagram is shown in Fig. 4.

The fundamental and harmonic components of the current in the primary winding of the test frame are obtained from measurements of the voltage across the standard resistor R_c, made with a wave analyzer tuned to respond only to the frequency of the particular harmonic under consideration.

The general equation used for calculating total core losses by the bridge method is equation 8.

$$\text{Total core loss} = I_1^2 R_d - \sum_3^k I_h^2 R_p = P_d$$

The terms of this equation were calculated from the data obtained in the measurements. The results are given in Table I and are presented in graphical form in Fig. 5. Neither the data from the wattmeter nor from the bridge have been corrected for instrument loss or form factor since these results are for comparison purposes only. The final column of Table I and the curves show that the two methods are in excellent agreement.

Summary and Conclusion

The use of an a-c bridge for measuring core loss has some advantages over the conventional wattmeter method, such as a wider frequency range and better sensitivity. However, it has been found that the bridge method is subject to errors which may be large if the effect of distortion in the magnetizing current is neglected. The correction for this may be obtained by considering the equivalent circuit for the ferromagnetic circuit element to consist of resistance, inductance, and a series of generators delivering current to the circuit at harmonic frequencies. This method requires that the apparent resistance of the entire circuit connected to these generators be determined, including the apparent resistance of the power source. The power dissipated in the ferromagnetic material is the power supplied to the material by the source at fundamental frequency minus the harmonic power the material returns to the circuit.

A circuit was devised by which measurements of core loss can be made by the bridge and wattmeter simultaneously. By so doing, discrepancies due to differences in frequency or induction are obviated and comparisons can be made at identical values of frequency and induction.

Excellent agreement between the two methods was obtained for inductions as high as those for which the wattmeter is considered to be accurate.

It is therefore concluded that even for measurements at higher inductions than have hitherto been considered feasible, accuracy of an a-c bridge is comparable with that of the wattmeter, provided that the corrections for harmonic components in the exciting current are determined and applied with care.

Discussion follows

Discussion

D. C. Dieterly (Research Laboratories, Armco Steel Corporation, Middletown, Ohio): This is a fine piece of work which demonstrates so convincingly that wattmeter and bridge methods can give equivalent values for core loss when the tests are conducted under similar conditions. Those of us who make core loss measurements at high inductions by wattmeter methods for grading of electrical steel, and also bridge tests at certain other inductions, have been aware that bridge methods can give fractional per-cent agreement with wattmeter methods when the test induction is limited to flux densities where the harmonic power is negligibly small compared to that for the fundamental frequency. In bridges designed recently we have provided much smaller resistance in the arm carrying the specimen's exciting current than was done years ago, and have also taken pains to keep the resistance of the test winding and of the power source low. We find that harmonic power can be made small enough to be neglected up to 12 kilogausses on conventional grades of electrical steel, and up to 16 kilogausses on the oriented product. Although we are not inclined to push the bridge test method to higher inductions because of the difficulties which then become of paramount importance, the authors have shown that it can be done.

Hesitancy to employ bridge methods at moderate and reasonably high inductions seems to stem from the belief that a large value of resistance is a necessity in series with the specimen, and that the resulting distortion of the flux wave form necessarily makes the results substantially in error. Also, under such conditions the user often questions whether the desired value of B_{max} was being achieved in the test, and whether the use of a balance only on the fundamental frequency was justifiable.

The authors have wisely incorporated the basic features of the Epstein wattmeter method into the bridge test, thereby preventing some procedural differences from clouding the issue. With the sensitive detection devices now available, the resistance in series with the unknown need not be much larger than that of the test winding itself. It might be well to point out to those not familiar with the work of Camilli (see reference 6 of the paper) that the use of the average-sensitive voltmeter (fluxvoltmeter) on an essentially unloaded secondary winding ensures that the correct value of B_{max} is reached if the test induction is calculated from the indications of such a meter, and likewise ensures that the hysteresis component of losses will be essentially the same as that for sinusoidal flux wave shape. Use of the true rms-reading instrument in conjunction with the fluxvoltmeter to determine the form factor of the induced voltage enables one to calculate the error in eddy-current component of losses caused by distortion of the induced voltage. Although this was not done in this work, not being a factor of difference in the two results, it is required procedure for tests made by the wattmeter method in accordance with American Society for Testing Materials practice. As for the question of balance only at the fundamental frequency, one must remember that in wattmeter measurements with essentially sinusoidal voltage on the potential coil windings, only power at fundamental frequency will produce torque on the instrument. Therefore the only difference (and the only factor which makes for difficult handling by the bridge method as it is currently used) is that harmonic distortion in the series resistance arm is reflected in the balance parameters and must be evaluated when of significant magnitude, as it was in the work undertaken by the authors.

In general, we believe that the simplicity of wattmeter measurements will probably confine the practical use of bridge tests at high inductions almost entirely to cases where wattmeter methods lack sensitivity or frequency range. Although rather costly a good reflecting type of wattmeter of very high sensitivity is available for use at frequencies up to 15 kc which enable wattmeter methods to be used over a greater range than is generally recognized. Having had both types of equipment available in the same laboratory for a number of years, we are inclined to use the bridge method for all a-c testing where data at 10 kilogausses (15 kilogausses on oriented materials) or less are of prime interest, and the wattmeter method where 10 kilogausses and higher are the inductions of interest.

While we believe that the modified Hay bridge circuit[1] offers much simpler procedure for obtaining values of magnetic properties by treating the magnetic core as a parallel combination of resistance and inductive reactance, and the winding resistance as a series resistance element, it is understandable that the authors chose the Maxwell circuit as a means of simplifying the proof in this particular approach. Perhaps someone will eventually find a way of taking care of the harmonic power in the bridge method which is simpler than the rather laborious procedure the authors have used successfully. Meanwhile, users of bridge methods will appreciate the wider field of usefulness encouraged for that instrument.

REFERENCE

1. See reference 2 of the paper.

I. L. Cooter and **W. P. Harris:** Mr. Dieterly points out that the bridge method has generally been limited to use at inductions of 10 kilogausses or less. This, of course, is a direct result of the disagreement between the results obtained by the wattmeter and bridge in core loss measurement at higher induction. The method described in the paper should clarify the situation and make possible the use of the bridge at the highest induction. The paper also emphasizes the need for power sources having sine wave voltage output and low impedances, and the necessity for keeping the resistance in the loop containing the test frame and power source as low as possible. For the experiments reported, the resistance, including the source, ratio arm, wattmeter, leads, and test frames, was only 4.3 ohms. If this resistance is increased, as by using a 10-ohm ratio arm, the harmonic power correction increases at any given induction and becomes significant at a lower induction.

However, now that we have a method for determining the harmonic power correction, there is no longer any fundamental bar to the use of the bridge at any induction. The choice between wattmeter and bridge methods can now be based on convenience and suitability.

Nontracking Organic Insulations

R. S. NORMAN

A. A. KESSEL
NONMEMBER AIEE

Synopsis: A novel principle has been discovered which retards or completely eliminates the formation of conducting decomposition products in organic materials exposed to electric discharges. The application of this principle to several organic insulation materials has greatly increased their ability to withstand electric arcing.

MANY new and improved organic electric insulations have become available over the past decade. Recent emphasis has been on the development of materials with more versatile physical characteristics and with improved high-temperature properties. Comparatively little work has been published on the compounding and synthesis of organic materials to improve a fundamental weakness, namely, their tendency to carbonize and form a conducting track on exposure to electric arcing conditions. Olyphant,[1,2] and Yarsley and Grant[3,4] have made significant contributions to measurement techniques and to the understanding of the basic mechanism of track initiation and propagation, but their work has been primarily concerned with the available insulating materials.

This paper reports the discovery of a novel principle which greatly increases the resistance of organic insulations to damage from electric discharges by reducing or completely eliminating the formation of conducting decomposition products. This is accomplished by building into the organic material an oxidation mechanism which prevents carbonization. Laboratory test methods and results on insulating materials exposed to arcing conditions are reported; surface creepage in contaminated atmospheres, arc-tracking, and internal ionization failure are discussed.

Internal Oxidation Mechanism

Previous workers have pointed out that the resistance of organic materials to damage from electric arcing is largely determined by their initial chemical composition and the nature of the gaseous and solid decomposition products. Olyphant[1] stresses the importance of the ambient gas and gaseous products of decomposition, Yarsley and Grant[3] emphasize the amount and nature of the decomposition products, Warren[5] cites the adverse effect of materials with carbon-rich phenyl groups, and Albert[6] states that the formation of conducting carbon is retarded in the case of vulcanized fibre by the large percentage of oxygen in its cellulosic structure. This suggests that, as in ordinary combustion where a free supply of oxygen is effective in lessening the quantity of solid carbonaceous deposits, an adequate source of oxygen within an organic insulating material might substantially reduce the formation of carbonized tracks under arcing conditions. However, the successful application of this principle to specific organic insulations has not previously been reported in the literature.

The nontracking materials discussed herein utilize a unique and basic formulation. The active component, which contributes to the oxidation mechanism, is a material which can be physically interspersed throughout the bulk of the basic organic material. This operation normally takes place during the compounding of the fillers, plasticizers, etc., with the base material. Under the influence of electric discharge in close proximity with the insulation material containing this interspersed ingredient, a reaction takes place which has unusual effectiveness in preventing the accumulation of carbonaceous deposits.

It is believed that the high arc temperatures resulting from the electric discharges break down the organic components of the insulating material and simultaneously trigger the oxidation reaction to form volatile hydrocarbons and gaseous oxides of carbon. Because this prevents the formation of free carbon, no conducting track is formed, and the only effect is a very slow general erosion, see Fig. 1.

These results are confirmed by two general classes of tracking tests.[3] In the first class of test the resistance to surface creepage damage by localized sparking is measured under contaminated conditions. This simulates outdoor use where nontracking elastomers and casting resins would have immediate application.

The second class of tracking test measures resistance to an arc drawn between two electrodes on the surface of a clean material.

Surface Creepage

Surface creepage in contaminated locations is a primary concern of electric apparatus designers. Under conditions of moisture, salt fog, or dust, leakage currents may result which produce arcing on the exposed surface of the insulation.[7-9] Under these conditions conventional organic insulating materials break down to form localized carbon paths.

Laboratory tracking tests, to be valid, must closely duplicate the expected service conditions and, in addition, must be capable of rapid and reproducible results. Several workers have described accelerated laboratory creepage tests on porcelain insulators coated with moist synthetic dusts containing a small amount of electrolyte and an insoluble binder.[9-11]

Various types of tracking tests as performed on organic insulating materials are discussed by Yarsley and Grant.[3] Their discussion includes tests in which scintillations are initiated by passing current through dust deposits between electrodes and tests in which current is passed through a drop of electrolyte between electrodes.

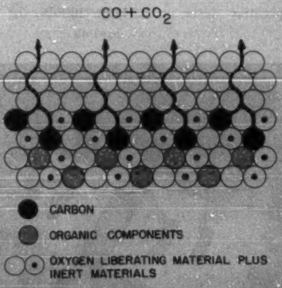

Fig. 1. Internal oxidation mechanism for elimination of tracking in organic insulating materials

Paper 55-699, recommended by the AIEE Dielectrics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 3-7, 1955. Manuscript submitted June 6, 1955; made available for printing September 16, 1955.

R. S. NORMAN, R. A. PFUNTNER, and A. A. KESSEL are with the General Electric Company, West Lynn, Mass.

Appreciation is expressed to M. W. Albright, D. E. Crawford, A. C. Bluestein, and the many others who contributed to this development. The encouragement and counsel offered by Dr. T. O. Paine during this investigation are greatly appreciated. Acknowledgement is also expressed to the Chemical Materials Department of the General Electric Company for compounding and evaluating phenolic materials utilizing the internal oxidation mechanism.

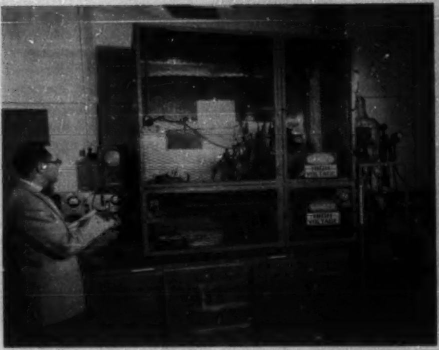

Fig. 2. Test equipment to study creepage resistance by dusted-sheet sample technique

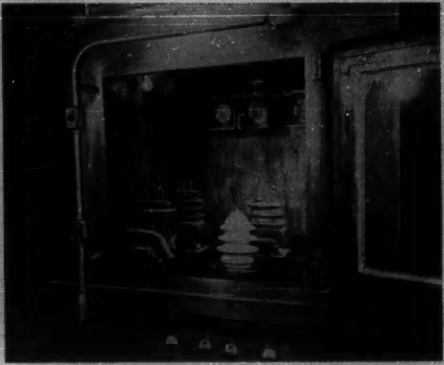

Fig. 4. Laboratory salt-fog chamber used primarily for creepage study of actual products

ACCELERATED SURFACE CREEPAGE TESTS

Based on this and other previous work, two modified tests were developed to evaluate creepage resistance under accelerated conditions. One test employs the moist dust principle and the other utilizes a salt fog.

In the dusted sample test, Fig. 2, a 75-mil sheet of the material to be tested is placed on a metal ground plate. Two parallel bar electrodes are spaced 1 inch apart on the insulation sheet. One electrode is connected to the ground plate, and a voltage of 1,500 volts is applied between the other electrode and ground. A partially conducting synthetic dust is placed on the insulation surface and continuously moistened with a tap-water spray. Under these conditions scintillations are constantly maintained between the electrodes; see Fig. 3. This relatively simple setup gives a rapid, reproducible means of making comparative tests on a large number of materials. However, the method is not readily applicable to actual apparatus having a complicated surface configuration.

The second accelerated test utilizes a salt-fog chamber continuously supplied with a dense fog of 10-per-cent NaCl and 1.2-per-cent MgCl. This chamber is used primarily for testing actual apparatus; see Fig. 4. A direct correlation between this test and severe coastal conditions is described in a companion paper.[7]

RESULTS OF ACCELERATED TESTS

Conventional Materials

Table I shows the time to failure of some typical organic insulations exposed to the dusted sample test. The results of tests on several samples of each material were very consistent except in the case of filled epoxide resin which is discussed in the following. The appearance of several samples is shown in Fig. 5.

It was observed that once an initial spot is carbonized from the arcing, this spot serves as a starting point for further degradation and a surface carbonized path forms at an ever-increasing rate. Because it is difficult to make filled epoxide samples without an appreciable resin skin on at least one surface, epoxide results tend to be erratic. When the tests are made on a surface having a heavy filler concentration (the bottom side as cast), the 40-hour time to failure is observed, but the other less filled surfaces invariably fail in less than 1 hour. The appearance of the melted glass in the melamine glass laminate sample, Fig. 5, indicates the high arcing temperatures produced by this test. In addition to many organic materials, silicone rubber was tested and gave excellent results as expected from its basic inorganic structure.

The surface tracking observed in the dusted sample test is also found in the salt-fog test. There is some variation between the resistance of materials to the two tests. For example, butyl

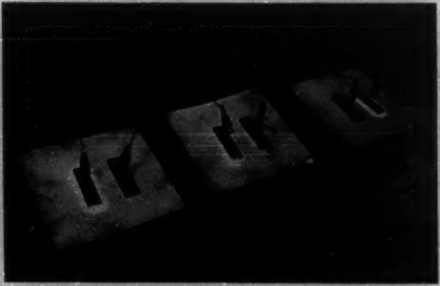

Fig. 3. Insulation sheet samples undergoing creepage test

Table I. Dust-Creepage Test on 75-Mil Conventional Organic Materials

Material	Hours to Failure
Silicone glass laminate	0.2
Filled polyester	0.2
Vulcanized fibre	0.3
Polyvinyl chloride	0.5
Neoprene	1.0
Melamine glass laminate	1.0
Hypalon *S-2*	1.0
Filled butyl rubber	2.0
Polyurethane	8.0
Melamine formaldehyde	12.0
Fluorinated rubber	18.0
Filled epoxide	0.5 to 40

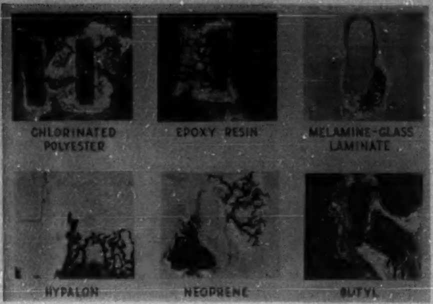

Fig. 5. Conventional organic insulations after exposure to the dusted sample creepage test

rubber is much more resistant to creepage damage in salt fog than epoxide resin. Transformers molded in conventional butyl rubber and cast in conventional epoxide resin are shown in Fig. 6 after exposure to accelerated arcing in the salt-fog test. Conventional butyl rubber transformers failed after 90 hours in the salt fog; the conventional epoxide transformers lasted less than 1 hour.

Based on the foregoing work, the following general sequence is suggested as leading to creepage failure of filled organic materials. The high localized temperatures produced by repeated sparking on the surface of the insulating material breaks down the organic components to form carbon. The exposed carbon at the surface is oxidized and goes off as a gas; see Fig. 7. The inert fillers left behind now form a blanket over the surface. As the remaining organic material breaks down, the blanket of filler prevents complete oxidation of the carbon. The unoxidized carbon accumulates and forms a conducting path under the inorganic filler; see Fig. 8.

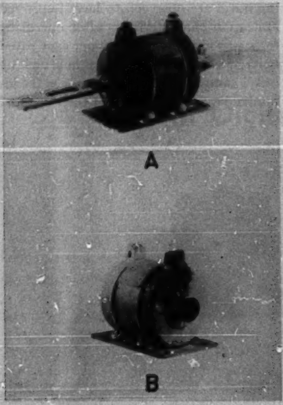

Fig. 6. Conventional butyl and epoxide insulated transformers after laboratory salt-fog test at 600 volts

A—Conventional butyl, surface-creepage failure in 90 hours

B—Conventional epoxide, surface-creepage failure in 1 hour

Fig. 9 shows an enlarged cross-sectional view of the failure path of a conventional butyl-insulated transformer after the salt-fog test. The appearance of the cross section provides evidence for the aforementioned mechanism. Although the protecting skin exists only with filled materials, the basic premise of carbon formation resulting from insufficient oxygen appears valid for all organic insulations.

Materials Utilizing Internal Oxidation Mechanism

Table II shows the improvement obtained on the dusted sample test by utilizing the internal oxidation mechanism in three conventional materials. The appearance of the samples after test is shown in Fig. 10.

No carbon spots form on butyl rubber or epoxide resin and, consequently, there is no concentration of the sparking along carbonized paths. Although a few carbonized spots were visible on the neoprene, in all cases failure ultimately occurred by erosion through the thickness of the samples. Obviously the time-to-erosion failure of the nontracking materials can be lengthened by increasing the thickness, while the time-to-tracking failure of conventional insulating materials is a function of the length of time required for a carbon track to progress across the surface of the insulation.

Similar results are obtained in the salt-fog tests. A typical example of the improvement obtained with the nontracking materials is illustrated by Fig. 11. One of these identical 600-volt transformers is insulated with conventional silica-filled epoxide resin, and the other with epoxide resin employing the internal oxidation mechanism. While the conventional epoxide insulation formed a carbonized path and failed after 1 hour at 600 volts in the salt-fog chamber, the nontracking material exhibited no carbon tracking, and finally failed by erosion after 1,400 hours under the same conditions. The life could have been extended even beyond this time by increasing the insulation thickness.

Fig. 12 shows a conventional butyl rubber transformer, a nontracking butyl rubber transformer, and a 15-kv porcelain bushing after exposure in the salt-fog chamber at 5 kv. Although the conventional butyl failed by carbon tracking in 107 hours, no carbonization was visible on the nontracking butyl after 1,400 hours. The failure of the 15-kv porcelain bushing, caused by cracking from thermal shock after 432 hours at 5 kv, emphasizes the severity of this accelerated test.[7]

A direct correlation between the accelerated salt-fog chamber tests and the most adverse service conditions found in the United States has been obtained for 5,000-volt butyl instrument transformers. Nontracking butyl does not carbonize

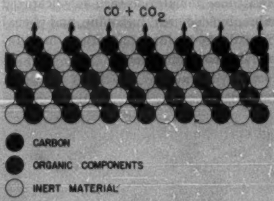

Fig. 7. Creepage failure of filled organic material, initial surface oxidation

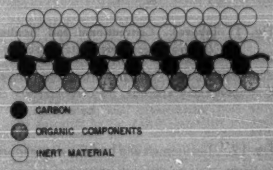

Fig. 8. Creepage failure of filled organic material, formation of carbonized path

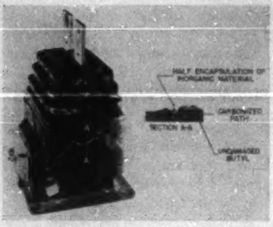

Fig. 9. Creepage failure of a conventional butyl transformer showing enlarged cross section of failure path

under either condition; conventional butyl, which fails in approximately 100 hours in the salt-fog chamber, lasts approximately 1,500 hours at the most severe outdoor location, an oceanside test station in San Francisco.[7]

Arc Tracking—ASTM

The elimination of carbonization by the internal oxidation mechanism is not only effective in reducing creepage damage but also greatly increases the arc resistance of organic materials. The standard test for arc resistance is the American Society for Testing Materials (ASTM) *495-48T* arc-resistance test,[12] in which a high-voltage low-current arc is drawn between two pointed electrodes on the surface of a clean material. This test is generally accepted for evaluating the arc resistance of materials such as vulcanized fibre, molded urea, melamine, and phenol formaldehyde for applications not involving contamination.

Table II. Dust-Creepage Test on 75-Mil Samples

Base Material	Hours to Failure	
	Conventional Filled	Utilizing Internal Oxidation Mechanism
Butyl rubber	2.0	400
Epoxide resin	0.5 to 40	400
Neoprene	1.0	31

The application of the internal oxidation mechanism to phenolics is of particular interest because of the widespread use of these materials. For example, W. Vassar and C. Leff[13] have recently drawn attention to the desirability of a low-cost arc-resistant phenolic-type material. Although phenolics are widely used by the electrical industry, their arc-tracking resistance is notoriously poor.[4] Previous workers have suggested that the high carbon content of the phenyl group[5] and the tarry decomposition products contribute to this poor tracking resistance.[1,3]

The internal oxidation mechanism has been applied to phenolics and has proved highly effective. Conventional wood-flour-filled phenolics have an arc resistance of 2 to 5 seconds, while conventional filled urea formaldehyde and melamine formaldehyde, which are normally felt to have good arc resistance, are in the range of 125 seconds.[14] With the internal oxidation mechanism the arc resistance of phenolics is increased from the previous 2 to 5 seconds to values of 180 to 190 seconds. Table III compares the ASTM arc resistance of conventional materials with phenolics using the internal oxidation mechanism.

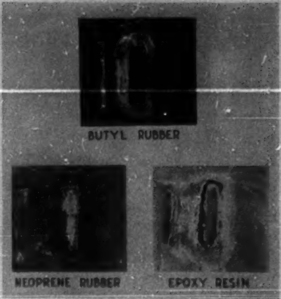

Fig. 10. Materials utilizing the internal oxidation mechanism after exposure to the dust-creepage test

Exploratory Work on Internal Ionization

When insulating materials are subjected to high-voltage stress, ionization will take place if internal voids are present and located in critical areas. Excessively severe internal ionization usually leads to rapid dielectric failure.[15] The internal oxidation mechanism, which has been shown to prevent surface carbonization, might also be expected to retard internal ionization and carbonization. Limited data on butyl rubber confirm the existence of this effect.

Transformers insulated with nontracking butyl are observed to have improved ionization characteristics after operating for a period of time at 300-per cent rated voltage. In addition, several nontracking butyl samples with molded-in electrodes retained over 50 per cent of their original

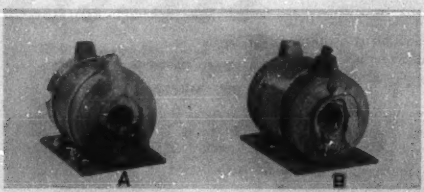

Fig. 11 (above). Conventional and nontracking epoxide-insulated 600-volt transformers after exposure to salt-fog test

A—Conventional epoxide, carbonized failure in less than 1 hour

B—Nontracking epoxide, no carbonization after 1,400 hours, failure by erosion

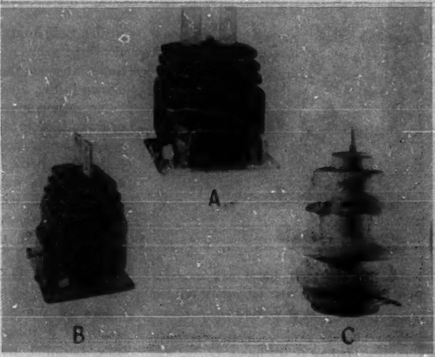

Fig. 12. Transformers and bushing after exposure to salt-fog test at 5 kv

A—Nontracking butyl transformer, no carbonization after 1,400 hours

B—Conventional butyl transformer, carbonized surface failure after 107 hours

C—Fifteen-kv porcelain bushing, cracked and chipped after 400 hours dielectric strength after internal failure on a 60-cycle high-potential test. This is apparently related to the absence of internal carbonization and to the formation of gas under pressure in the failure-path cavity.

An interesting experiment was conducted with a hypodermic needle inserted between the electrodes which confirmed the presence of gas under pressure after the initial breakdown. As long as the hypodermic needle was open to the atmosphere, the gas formed internally could not build up pressure, and the sample showed only the dielectric strength of air at atmospheric pressure. When the needle was closed to the atmosphere, the voltage could be raised slowly to over 50 per cent of the original breakdown value. By opening the hypodermic needle gas was released and the dielectric strength again dropped to the value for air. This cycle was repeated several times with the same results. A further study of this effect is progressing to obtain a better understanding of this phenomenon.

Summary

It has been discovered that the application of the internal oxidation mechanism to organic materials is highly effective in preventing carbonization under arcing conditions. Greatly improved resistance to surface-creepage damage has been observed in laboratory tests and under severe outdoor exposures. The formation of carbonized tracks is eliminated under these conditions. Standard ASTM arc-tracking tests indicate that phenolics using this mechanism can now be made superior to the best conventional arc-resistant molding compounds. The internal oxidation mechanism has also been observed to prevent the formation of conducting carbon following an internal dielectric failure.

Table III. ASTM 495-48T Arc-Resistance Test

Material	Average Time, Seconds
Phenolic	4
Urea	125
Melamine	125
Vulcanized fibre	125
Phenolic utilizing internal oxidation mechanism	185

Transformer Reactance Calculations with Digital Computers

L. RABINS
ASSOCIATE MEMBER AIEE

SINCE one of the important features of a transformer is its series or leakage impedance, improvements in the calculation of this quantity are always searched for. In power transformers this impedance is almost all formed by its reactive component so that the accuracy of the impedance calculation hinges on the accuracy of the leakage reactance calculation. Modern methods of calculation using digital computers have been adopted so that very accurate reactance calculations can be made whenever they may be required in the design of a particular transformer. The use of a digital computer makes this calculation quick, easy, and painless, and permits a major improvement in this phase of transformer design.

In a cylindrical coil-core type of transformer, most of the difficulties in reactance calculation stem from axial ampere-turn discontinuities and unbalance between windings. The reactance of normal transformer designs in which both of these occur to a slight extent is accurately calculated by simple design equations. However, the design which may occur, for example, because of the request for extraordinary impedance relationships in a 3-winding transformer or as to parallel with a transformer having a peculiar impedance variation with the voltage tap position, leads to unusual axial ampere-turn distributions. This problem has been considered in the past,[1–5] but except for Roth's work[6] and unpublished work done within the General Electric Company by Liebinger, Poritsky, and Tino, there has been no consideration given the dual problem of axial ampere-turn distribution and the effect of curvature. It has become apparent that these two effects must be considered together and not separately, as in the past. Also in the past, investigators looked for simplification of rigorous equations. In the present work, the search has been for an accurate method adaptable to a digital-computer calculation.

Roth's analysis of this dual problem has followed in principle his double

Y., January 30–February 3, 1956. Manuscript submitted September 29, 1955; made available for printing November 18, 1955.

L. Rabins is with the General Electric Company, Pittsfield, Mass.

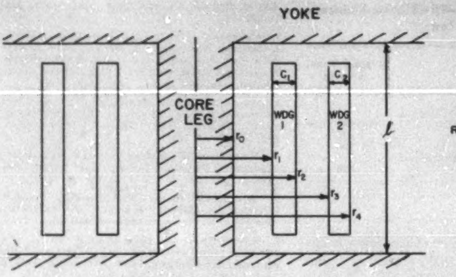

Fig. 1. Transformer with two cylindrical windings

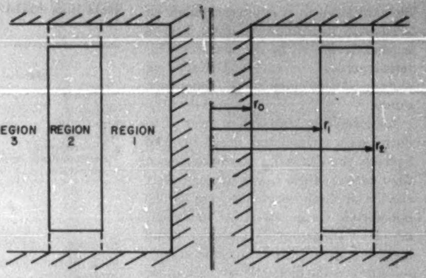

Fig. 2. Transformer with only one cylindrical winding shown

Fourier series method,[7] which he earlier applied to a reactance calculation in which curvature was neglected. With curvature considered, his analysis results in expressions difficult to evaluate not only because Bessel functions are involved but because the arguments of these functions are themselves functions of boundary dimensions and are found by solution of certain transcendental equations.

This paper is concerned with another and simpler form of solution to this problem, very similar in principle to Rogowski's[8] single Fourier series method, and classical methods of solution are employed.[9] The solution presented herein is in the form of a Fourier series the coefficients of which are Bessel and Struve functions, all of which are functions readily programmed for computation by an International Business Machines (IBM) card-programmed calculator.

The basic building block in the reactance calculation of any transformer is that between two windings. The reactance of any combination of windings can then be found by other methods, the most useful being that given by Garin and Paluev.[10] Only the basic 2-winding reactance calculation is being considered herein.

Outline of Problem and Method of Analysis

Fig. 1 shows a transformer with two cylindrical windings. The yokes above and below the coils are assumed of infinite extent and are completely circular so as to fully cover the windings. This permits the use of a Fourier series to describe the axial ampere-turn distribution of each winding. The general differential equations describing a magnetic field[11] are set up and the solution for the vector potential (which has only an angular component) is found. The magnetic field energy[11] can now be computed and the leakage inductance found.

Results and Calculations Procedure

The final equation used to compute reactance is

$$\%X=\frac{0.126f\text{ kva}}{e^2}\frac{(\Sigma NI)^2}{l}\times\left((Dr)+\frac{C_1^2-C_2^2}{12}\right)+\frac{0.063f\text{ kva }l}{e^2}\times\sum_{n=1}^{\infty}\left(\frac{I_{1n}(\text{pu})}{m^2C_1}\right)^2\left[\int_0^{x_2}xK_1dx\times\int_{x_1}^{x_2}xI_1dx+\left(\frac{I_0(x_0)}{K_0(x_0)}\int_{x_1}^{x_2}xK_1dx-\int_0^{x_1}xI_1dx\right)\int_{x_1}^{x_2}xK_1dx-\frac{\pi}{2}\int_{x_1}^{x_2}xL_1dx\right]+\left(\frac{I_{2n}(\text{pu})}{m^2C_2}\right)^2\times\left[\int_0^{x_4}xK_1dx\int_{x_3}^{x_4}xI_1dx+\left(\frac{I_0(x_0)}{K_0(x_0)}\int_{x_3}^{x_4}xK_1dx-\int_0^{x_4}xL_1dx\right)\times\int_{x_3}^{x_4}xK_1dx-\frac{\pi}{2}\int_{x_3}^{x_4}xL_1dx\right]+2\frac{I_{1n}(\text{pu})I_{2n}(\text{pu})}{m^4C_1C_2}\int_{x_3}^{x_4}xK_1dx\times\left(\frac{I_0(x_0)}{K_0(x_0)}\int_{x_1}^{x_2}xK_1dx+\int_{x_1}^{x_2}xI_1sx\right)\quad(1)$$

where

f = frequency, cycles per second
kva = kilovolt-ampere per core leg
e = volts per turn
l = axial length over which ampere-turn distribution is defined; will usually be either half or the whole distance between yokes
ΣNI = sum of per-unit (pu) ampere-turns in a coil stack
C_1, C_2 = radial builds of windings 1 and 2
Dr = effective area of leakage field for completely uniform flux field
$=[(r_2+r_1)/2](C_1/3)+[(r_3+r_2)/2]g+[(r_4+r_3)/2](C_2/3)$
g = radial gap between windings = r_3-r_2
n = index over which series is summed = 1, 2, 3, ...
$m=(n\pi)/l$
r_0, r_1, r_2, r_3, r_4 = radii defined by Fig. 1
$x=mr$
I_{1n}, I_{2n} = harmonics of the pu ampere-turn per inch distribution of windings 1 and 2
I_1, K_1, L_1 = modified Bessel and Struve functions of first order

The first term of the reactance equation results from the average ampere-turns in each winding, the average being taken over the length l. Flux lines corresponding to this reactance flow in a completely uniform vertical pattern over the entire length l and the reactance derivation is quite simple, appearing in several references,[12] so it will not be presented here. The remaining terms result from the nonuniform axial ampere-turn distribution. For most designs, symmetry exists about the axial centerline so that calculations may be made on a half-stack basis. If calculations are based on 1 pu ampere-turn in a full coil stack and the length l is half the distance between yokes, the same equation multiplied by 2 is used.

The harmonic coefficients of the ampere-turn distribution are given by (see Appendix I)

$$I_n=\frac{2}{n\pi}(\delta_{a-b}\sin ma+\delta_{b-c}\sin mb+\ldots\delta_{l-d}\sin md)\quad(2)$$

The calculation is performed on an IBM card-programmed calculator in a 10-digit floating decimal system. The calculation program is divided into two steps. First is the calculation of the harmonic coefficients. Here each winding is considered separately and broken into a minimum number of sections, each section having uniform ampere-turns pu axial height. The dimensions and total pu ampere-turns of each section are punched on IBM cards and are input data to the calculator. The program is arranged to handle any number of sections and, by omitting parts of the program deck, the length of the calculation is made proportional to the number of sections. After the first harmonic is evaluated, the integer n is advanced one, and an identical calculation is made, and this procedure is repeated until all necessary harmonics have been calculated. Harmonic coefficients are found for both windings in this fashion.

Following this, the actual reactance calculation is made. This requires additional input, frequency, kva per leg, volts per turn, and all radial dimensions beginning at the center line of the core and extending to the outer winding. The harmonic coefficients are also necessary input. These coefficients will have been punched on IBM cards during their calculation. Calculation then proceeds through the evaluation of the Bessel and Struve functions and the reactance, one harmonic at a time, each harmonic calculation procedure again being identical except for a change in harmonic order.

Derivation of Reactance Equation

The following is assumed in the derivation:

1. The yoke is infinitely large, completely covers top and bottom of the windings, and has infinite permeability.
2. Circular symmetry exists.
3. The effect of adjacent windings and core legs, tank walls, and current-carrying leads is negligible.
4. The field is unbounded radially.
5. The core leg is round and has infinite permeability.
6. Each winding is uniform radially.
7. The effect of normal ducts and insulation between coil sections is negligible.
8. The sum of the total ampere-turns in the two windings is zero.

The field equations appropriate to this problem of reactance calculation are

$$\nabla\cdot\mathbf{B}=0$$

$$\nabla\times\mathbf{H}=\mathbf{i}$$

$$\mathbf{B}=\mu\mathbf{H} \tag{3}$$

where **B**, **H**, and **i** are flux density, magnetic field strength, and current density respectively. Meter-kilogram-second units are used. Define a vector potential by

$$\nabla\times\mathbf{A}=\mathbf{B}$$

$$\nabla\cdot\mathbf{A}=0 \tag{4}$$

Substituting the foregoing results in[11]

$$\nabla^2\mathbf{A}=-\mu\mathbf{i} \tag{5}$$

The vector **i** defines the current density in the winding and since it has only an angular component, this will also be the only component of the vector potential. Denoting this component by the subscript

$$\nabla^2 A_\theta=-\mu i_\theta \tag{6}$$

In circular co-ordinates this becomes

$$\frac{\partial^2 A_\theta}{\partial r^2}+\frac{1}{r}\frac{\partial A_\theta}{\partial r}-\frac{A_\theta}{r^2}+\frac{\partial^2 A}{\partial z^2}=-\mu i_\theta \tag{7}$$

Describe the current density by a Fourier series (see Appendix I)

$$i_\theta=i_0+\sum_{n=1}^{\infty} i_n\cos mZ \tag{8}$$

where $n=1, 2, 3, \ldots$. Assume that the vector potential can be similarly developed

$$A_\theta=A_{0(r)}+\sum_{n=1}^{\infty} A_{n(r)}\cos mZ \tag{9}$$

Substituting the foregoing, a set of equations is obtained

$$\frac{d^2A_0}{dr^2}+\frac{1}{r}\frac{dA_0}{dr}-\frac{A_0}{r^2}=-\mu i_0 \tag{10}$$

$$\frac{d^2A_n}{dr^2}+\frac{1}{r}\frac{dA_n}{dr}-\frac{A_n}{r^2}-m^2A_n=-\mu i_n \tag{11}$$

for each n. This set of equations is obtained because of the orthogonality of $\cos mZ$. The first of these equations is easy to solve and corresponds to flux flowing in only the Z-direction. The reactance resulting from this component of the vector potential is the first term in the reactance equation previously given in the section entitled "Results and Calculation Procedure." It is the set of equations for general n which is mostly of interest. If the right-hand side of the foregoing equation were zero, the equation would be recognized as Bessel's and the solution would be[13]

$$A_n=CI_1(mr)+DK_1(mr) \tag{12}$$

where I_1 and K_1 are modified Bessel functions of the first and second kind, first order. A particular solution to the complete equation may be found by the method of quadratures[16] or by recognition that it is satisfied by a modified Struve function $L_1(mr)$.[13–15] The complete solution for general n is then

$$A_n=CI_1(mr)+DK_1(mr)-\frac{\pi\mu i_n}{2m^2}L_1(mr) \tag{13}$$

C and D are constants determined by boundary conditions. Consider one winding at a time and the three regions defined by Fig. 2. The solutions to the differential equations in the three regions are given respectively as

$$A_{1n}=C_1I_1(mr)+D_1K_1(mr)$$

$$A_{2n}=C_2I_1(mr)+D_2K_1(mr)-\frac{\pi\mu i_n}{2m^2}L_1(mr)$$

$$A_{3n}=C_3I_1(mr)+D_3K_1(mr) \tag{14}$$

The boundary conditions reveal information which permit evaluation of the constants C and D. These stem from continuity of the flux densities. From the definition of the vector potential

$$B_r=-\frac{\partial A_\theta}{\partial Z}$$

$$B_Z=\frac{1}{r}\frac{\partial rA}{\partial r} \tag{15}$$

At the iron boundaries, the tangential flux is zero since infinite permeability iron was assumed. Thus

$$B_r=0 \text{ at } Z=\pm l \tag{16}$$

This yields the equation

$$\sum_{n=1}^{\infty}-mA_n\sin ml=0$$

or

$$m=\frac{n\pi}{l}, n=1, 2, 3, \ldots \tag{17}$$

The other boundary conditions are

$$B_Z=0 \text{ at } r=r_0$$

$$B_{1Z}=B_{2Z};\ B_{1r}=B_{2r} \text{ or } A_{1n}=A_{2n} \text{ at } r=r_1$$

$$B_{2Z}=B_{3Z};\ B_{2r}=B_{3r} \text{ or } A_{2n}=A_{3n} \text{ at } r=r_2$$

$$B_Z \text{ or } A_Z\rightarrow 0 \text{ as } r\rightarrow\infty \tag{18}$$

The last condition requires that

$$C_3=0 \tag{19}$$

since $I_1(mr)$ is an exponentially increasing function.

For any value n, the general value of B_{Zn} is

$$B_{Zn}=m\left(CI_0(mr)-DK_0(mr)-\frac{\pi\mu i_n}{2m^2}L_0(mr)\right) \tag{20}$$

Let $mr=x$ and

$$-\frac{\pi\mu i_n}{2m^2}=i_n' \tag{21}$$

Substitute the remaining boundary conditions in the equations 14 and 20 for A_n and B_{Zn} to obtain

$$C_1I_0(x_0)-D_1K_0(x_0)=0$$

$$C_1I_1(x_1)+D_1K_1(x_1)=C_2I_1(x_1)+D_2K_1(x_1)+i_n'L_1(x_1)$$

$$C_1I_0(x_1)-D_1K_0(x_1)=C_2I_0(x_1)-D_2K_0(x_1)+i_n'L_0(x_1) \quad (22)$$

$$D_3K_1(x_2)=C_2I_1(x_2)+D_2K_1(x_2)+i_n'L_1(x_2)$$

$$-D_3K_0(x_2)=C_2I_0(x_2)-D_2K_0(x_1)+i_n'L_0(x_2)$$

Utilize the equations

$$I_0(x)K_1(x)+I_1(x)K_0(x)=\frac{1}{x} \text{ (see reference 13)}$$

$$x[L_1(x)K_0(x)+L_0(x)K_1(x)]=\frac{2}{\pi}\int_0^x xK_1(x)dx$$

$$x[L_1(x)I_0(x)-L_0(x)I_1(x)]=\frac{-2}{\pi}\int_0^x xI_1(x)dx \quad (23)$$

The origin of the latter equations is covered in Appendix II. Solving for C and D

$$C_1=\frac{\mu i_n}{m^2}\int_{x_1}^{x_2} xK_1dx$$

$$C_2=\frac{\mu i_n}{m^2}\int_0^{x_2} xK_1dx$$

$$D_1=\frac{I_0(x_0)}{K_0(x_0)}\,\frac{\mu i_n}{m^2}\int_{x_1}^{x_2} xK_1dx \quad (24)$$

$$D_2=\frac{I_0(x_0)}{K_0(x_0)}\,\frac{\mu i_n}{m^2}\int_{x_1}^{x_2} xK_1dx-\frac{\mu i_n}{m^2}\int_0^{x_1} xI_1dx$$

$$D_3=\frac{I_0(x_0)}{K_0(x_0)}\,\frac{\mu i_n}{m^2}\int_{x_1}^{x_2} xK_1dx+\frac{\mu i_n}{m^2}\int_{x_1}^{x_2} xI_1dx$$

The solution for the vector potential is now complete.

Consider now that two windings are present, as shown in Fig. 1. Two solutions of the same form as that just found may be superimposed by properly identifying regions 1, 2, and 3. The space harmonics of the ampere-turn distribution of windings 1 and 2 will be represented by i_{1n} and i_{2n} respectively. In the region occupied by winding 1

$$A_{1n}=\frac{\mu i_{1n}}{m^2}\Bigg[I_1(x)\int_0^{x_2} xK_1dx+K_1(x)\times\left(\frac{I_0(x_0)}{K_0(x_0)}\int_{x_1}^{x_2} xK_1dx-\int_0^{x_1} xI_1dx\right)-\frac{\pi}{2}L_1(x)\Bigg]+\frac{\mu i_{2n}}{m^2}\left(I_1(x)\int_{x_3}^{x_4} xK_1dx+K_1(x)\frac{I_0(x_0)}{K_0(x_0)}\int_{x_3}^{x_4} xK_1dx\right) \quad (25)$$

In the region occupied by winding 2

$$A_{2n}=\frac{\mu i_{2n}}{m^2}\Bigg[I_1(x)\int_0^{x_4} xK_1dx+K_1(x)\times\left(\frac{I_0(x_0)}{K_0(x_0)}\int_{x_3}^{x_4} xK_1dx-\int_0^{x_3} xI_1dx\right)-\frac{\pi}{2}L_1(x)\Bigg]+\frac{\mu i_{1n}}{m^2}K_1(x)\left(\frac{I_0(x_0)}{K_0(x_0)}\times\int_{x_1}^{x_2} xK_1dx+\int_{x_1}^{x_2} xI_1dx\right) \quad (26)$$

REACTANCE DERIVED FROM VECTOR POTENTIAL

With the vector potential known, the leakage inductance may be found by evaluating the energy stored in the magnetic field. If W is the magnetic field energy, and L the inductance[11]

$$W=\frac{1}{2}LI^2=\frac{1}{2}\iiint \bar{\mathrm{i}}\cdot\bar{\mathrm{A}}dv \quad (27)$$

Both $\bar{\mathrm{i}}$ and $\bar{\mathrm{A}}$ have only angular components each given by a Fourier series. dv is a differential volume $=rd\theta dZdr$.

Thus

$$\iiint \mathrm{i}\cdot\bar{\mathrm{A}}dv=\iiint\left(i_0+\sum_{n=1}^{\infty}i_n\cos mZ\right)\times\left(A_0+\sum_{n=1}^{\infty}A_n\cos mZ\right)dv \quad (28)$$

In the integration all terms not of the same order go to zero since

$$\int_0^l \cos m_1Z\cos m_2Z\,dZ=l/2 \quad (29)$$

if $m_1=m_2$, or equals zero if $m_1\neq m_2$.

This leaves

$$\iiint \mathrm{i}\cdot\mathbf{A}dv=l\iint i_0A_0rd\theta dr+\sum_{n=1}^{\infty}l/2\iint i_nA_nrd\theta dr \quad (30)$$

Carrying the integration over only the windings since it is only here that $i\neq0$ and omitting the first term in the foregoing

$$L=\frac{\iiint \mathrm{i}\cdot\mathbf{A}dv}{I^2}=\sum_{n=1}^{\infty}\frac{l}{2I^2}\int_0^{2\pi}\int_{r_1}^{r_2} i_{1n}A_{1n}rd\theta dr+\int_0^{2\pi}\int_{r_3}^{r_4} i_{2n}A_{2n}rd\theta dr \quad (31)$$

Except for the integral of the Bessel functions, a typical term of this expression has the coefficient

$$\mathrm{coef}_L=\frac{\pi l\mu i_{1n}i_{2n}}{m^4I^2} \quad (32)$$

Refer both windings to ones with an equal number of turns N. Then, with the current density being uniform over the radial build, it may be written as

$$i_{1n}=\frac{I_{1n}}{C_1} \quad (33)$$

where I_{1n} is the ampere-turns pu axial length. Then

$$\mathrm{coef}_L=\frac{\pi l\mu I_{1n}I_{2n}}{C_1C_2m^2I^2} \quad (34)$$

Multiplying numerator and denominator by N^2 and recognizing

$$I_{1n}/(NI)=I_{1n}(\mathrm{pu})=\text{pu ampere-turns pu axial length} \quad (35)$$

$$\mathrm{coef}_L=\frac{\pi l\mu N^2I_{1n}(\mathrm{pu})I_{2n}(\mathrm{pu})}{C_1C_2m^4} \quad (36)$$

This is the coefficient of an expression for the leakage inductance; to change to per-cent reactance multiply by

$$2\pi f\,10^5\frac{\mathrm{kva}}{V^2} \quad (37)$$

where

V = the rated voltage of a winding
kva = kva rating of a winding
f = frequency

The foregoing coefficient has a length dimension to the first power; changing from meters to inches and using the permeability of free space of $4\pi\times10^{-7}$

$$\mathrm{coef}_{\%X}=0.063\frac{f\,\mathrm{kva}\,l}{(V/N)^2}I_{1n}(\mathrm{pu})I_{2n}(\mathrm{pu}) \quad (38)$$

The final expression is now found by carrying out the integration in equation 31 for reactance and is given as equation 1.

Bessel Function Computation

The general process by which the Bessel and Struve functions were evaluated on the card-programmed calculator consisted of a computation using either a power or asymptotic series.

The card program is set up so that for low arguments a power series is used and for high arguments an asymptotic series. The changeover point is 6 for I_0, $\int xI_1dx$, and $\int xL_1dx$; and 3.5 for K_0 and $\int xK_1dx$. In general, 12 terms were used in the power series expansion, 7 or less in the asymptotic. To obtain a smooth transition of the integrals at the changeover point, it was necessary to adjust the last coefficient of the asymptotic series.

The general principle involved in the computation of the series was built on adding terms of the form

$$xC+D$$

each such operation being performed in one card cycle. A power series with seven terms

$$P=A_0+A_1x+A_2x^2+A_3x^3+A_4x^4+A_5x^5+A_6x^6$$

may be factored starting at the end to give

$$P=A+x[A_1+x(A_2+x\{A_3+x[A_4+x(A_5+xA_6)]\})]$$

so that it is seen that one card operation advances one term in the evaluation of the series. Based on a speed of 150

cards per minute, a 12-term series is evaluated in 5 seconds.

The coefficients of the series were evaluated by a desk calculator using general expressions.[13,14] The series for the integrals were found by direct integration of the power series and by repeated integration by parts of the asymptotic series.

The functions were calculated over the range 0 to 50 and compared to existing tables,[17–20] or to combinations of existing tables when direct comparison could not be done. Better than 5-place accuracy was obtained throughout.

It should be noted that considerable simplicity results in the determination of the series of the functions to be evaluated from the use of Struve functions and the recognition of the integrals which are equal to certain groups of Bessel and Struve functions. If the Struve functions were not used as a solution of the differential equation, but a solution built up by superposition and summation of the effect of current sheets, or if the solution had been left in the integral form given by the method of quadratures, the result for the reactance would have contained various combinations of terms such as

$$\int_{x_1}^{x_2} xK_1dx\int_{x_1}^{x} xI_1dx$$

which is not in a form in which the coefficients of the power or asymptotic series are readily found.

Test Results

Several comparisons between tests and calculated reactances on production transformers and models which were built to get an exaggerated ampere-turn distribution are listed in the following. These examples are all normally difficult to calculate. Fig. 3 shows the general winding configurations. The data within each block on the figures contain the pu ampere-turns (the top number) and the axial height of the block (the bottom number). Distances to the yoke and holes in a winding are shown as blocks with zero ampere-turns. All values of pu ampere-turns are based on a total of 1 pu ampere-turn in a stack. Table I summarizes the test results. In all cases the calculation was made through the tenth harmonic.

Table I. Test Results

Case	Kva	Per-Cent X	
		Test	Calculated
1	1.63	14.5	13.75
2	3.60	58.7	58.29
3	3.60	97.6	95.53
4	3.60	49.5	42.10
5	3.60	43.5	43.66
6	2.53	34.3	35.99

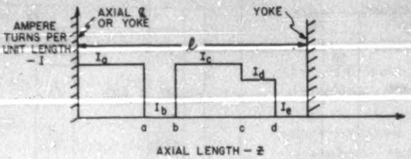

Fig. 4. Typical axial ampere-turn density plot

All calculations are based on a value of unity volts per turn and arbitrary kva. Frequency was 60 cycles per second. Case 6 involves a calculation between the inside winding and the other two in series. On a full-winding basis with the middle and outer windings sharing 1 pu ampere-turn, the turns are so divided that the total pu ampere-turns in the middle winding is 0.896 and in the outer 0.104. A complete reactance calculation requires three independent 2-winding calculations, each based on 1 pu ampere-turn in each winding. If the inner, middle, and outside windings are designated by the subscripts 1, 2, and 3 respectively, then the calculated impedance values are

$X_{1-2}=40.39$

$X_{1-3}=112.42$

$X_{2-3}=127.76$

Following the technique of Garin and Paluev,[10] the reactance

$$X_{1-23}=0.896X_{1-2}+0.104_{1-3}-(0.896)(0.104)X_{2-3}=35.99$$

It was not possible to test the values of these reactances individually.

Considering the extreme nature of the cases listed, accuracy is good with the maximum error of about 5 per cent. Some of this error may be due to manufacturing tolerances or slight errors in test.

Discussion and Conclusions

Equations and computational techniques for the calculation of the leakage reactance of core-type cylindrical transformer windings have been presented. While emphasis has been placed on the use in transformer design, the results are applicable to air-core reactors also.

The interpretation of the reactance equation is straightforward. Each harmonic contribution is seen to consist of two self-reactances terms and a mutual reactance term. The reactances are only that in a leakage field sense, i.e., they do not include the contribution of the core. This avoids the difficulty of finding a small leakage reactance by taking differences of very large reactances.

Concerning the assumptions used in the derivation, only two are of significance. The first concerns the yoke being considered to cover the windings and extending to infinity; whereas it actually covers only a portion of the windings. It has been found by comparison to test results that the position of the yoke has little effect, of the order of 3 per cent, if it is about 4 or more inches distant from the winding when the winding stack height is about 90 inches. Since this separation usually corresponds to the normal insulation distances, the actual distance to the yoke is used in the calculation as being the distance to the assumed infinite yoke. For any specific case, if it appears that it may cause error, calculations are made by arbitrarily changing the yoke distance over a large range and noting its effect on the reactance. A compensating effect which tends to counterbalance the reactance increased caused by the infinite yoke is the use of only ten harmonics in the reactance calculation. While normally only ten harmonics are required for accurate calculations, any number may be used. The second important assumption is the neglect of adjacent windings and tank walls. These corrections which are usually negligible are probably best handled empherically, though some qualitative effect may be found by locating a highly permeable or highly conducting cylinder outside the windings and by determining the reactances for these cases. The reactance equations for these conditions may be found by the same methods as described herein.

It should be emphasized that the one major item which makes the use of these accurate methods of reactance equations practical for regular design application is the modern high-speed digital computer.

Appendix I

A plot of the ampere-turns per unit axial height versus height is a series of straight-line sections, as shown in Fig. 4. Over the length l the ampere-turn density may be defined by a Fourier series

$$I=I_0+\sum_{n=1}^{\infty} I_n \cos mZ;\; m=\frac{n\pi}{l}$$

where

$$I_n=\frac{2}{l}\int_0^l I \cos mZdZ$$

Let

$\delta_{a-b}=I_a-I_b$

$\delta_{b-c}=I_b-I_c$, etc.

Equation 2 for the harmonic coefficients of the ampere-turn density immediately follows.

Appendix II

To prove the several relations in equation 23 certain equations are required for the derivatives of the Bessel and Struve functions[14]

$$\frac{d}{dx}I_0(x)=I_1(x)$$

$$\frac{d}{dx}K_0(x)=-K_1(x)$$

$$\frac{d}{dx}L_0(x)=\frac{2}{\pi}+L_1(x)$$

$$\frac{d}{dx}xI_1(x)=xI_0(x)$$

$$\frac{d}{dx}xK_1(x)=-xK_0(x)$$

$$\frac{d}{dx}xL_1(x)=xL_0(x)$$

It may now also be verified that the solution, equation 13, to the differential equation is correct. The integral relations given in equation 23 were first obtained by noting a general equation given by McLachlan and Meyers[21] for

$\int x^n I_n(x)dx$ and $\int x^n K_n(x)dx$

and by comparing the equation thereby obtained for

$\int I_0(x)dx$ and $\int K_0(x)dx$

to an integration by parts of

$\int xI_1(x)nx$ and $\int xK_1dx$

This procedure does not have to be followed here since the integrals may be verified by using the derivative equations in the foregoing and noting that

$$\frac{d}{dx}(xL_1(x)K_0(x)+xL_0(x)K_1(x))=\frac{2}{\pi}xK_1(x)$$

$$\frac{d}{dx}(xL_1(x)I_1(x)-xL_0(x)I_1(x))=-\frac{2}{\pi}xI_1(x)$$

By making use of the facts that for small values of x

$I_0(x)=1$

Vol.
Pt. 1
1956

$$K_0(x) = -ln\frac{x}{2}$$

$$L_0(x) = \frac{2x}{\pi}$$

$$I_1(x) = \frac{x}{2}$$

$$K_1(x) = \frac{x}{2}\, ln\frac{x}{2} + \frac{1}{x}$$

$$L_1(x) = \frac{2x}{3\pi}$$

it may be verified that the proper lower limit on the integral is zero since the left-hand side of equation 23 reduce to zero at $x=0$.

This is shown as

$$\{x[L_1(x)K_0(x) + L_0(x)K_1(x)]\}_{x=0}$$

$$= \lim_{x\to 0} x\left[\frac{-2x}{3\pi}\, ln\frac{x}{2} + \frac{2x}{\pi}\left(\frac{x}{2}\, ln\frac{x}{2} + \frac{1}{x}\right)\right] = 0$$

$$\{x[L_1(x)I_0(x) - L_0(x)I_1(x)]\}_{x=0}$$

$$= \lim_{x\to 0} x\left(\frac{2x}{3\pi} - \frac{x^2}{\pi}\right) = 0$$

It is necessary to determine proper limits on the integrals because the term to be evaluated is the left-hand side of equation 23, not the integral. The integral representation of this group of functions was used to obtain a faster calculation procedure since only two functions need be calculated rather than six.

Discussion

B. A. Cogbill (General Electric Company, Pittsfield, Mass.): The title of Mr. Rabins' paper might imply that he has done a more or less routine job of adapting a method of computing transformer reactance to digital computer calculations. However, it is obvious that this is a minor part of his accomplishment; more important is his mathematical analysis of the field problem.

It may be correctly argued that the field problem has been analzyed many times in the past by very capable investigators. But a thorough study of published material reveals that, in practically all cases, the earlier investigators were looking for simplification. Digital computers were unknown. So earlier efforts were directed toward obtaining expressions which were practical for use in calculating transformer reactance by methods available at the time. Hence, a number of simplifying assumptions were usually injected at an early stage of the analysis; the almost universal one being that curvature would be ignored. As a result, the use of the expressions for reasonably accurate calculations is quite restricted; and, even in the simpler cases, results are somewhat less accurate than those which could be obtained from use of more rigorous expression.

No doubt Mr. Rabins considered the existing expressions and their derivations. But knowing the capabilities of digital computers, he was confident that they could handle with comparative ease the more complicated calculations involved in the use of more rigorous methods. So, he chose the more difficult, but more rewarding, course of analyzing the field problem to obtain a solution which met his needs. This was accomplished in an admirable manner. The mathematical analysis of the field problem alone is an outstanding contribution and should be of interest to many engineers and practical mathematicians although they might not have any particular interest in digital computers.

The paper contains a number of comparisons between test values and values calculated on the digital computer using the author's method. As stated, these cases are of extreme nature. The author cited them to demonstrate the accuracy of the method under conditions for which other methods are known to be quite unreliable. But he had no intention of conveying the impression that the method is not practical for use in the more usual cases. Actually, a large number of reactances for power transformer designs have been calculated by the method; and it has proved to be a practical design tool.

The amount of data available for making a comparison between calculated and test values is much larger now than it was at the time the paper was written. Therefore a more realistic appraisal can be made by using only reactances of transformers which have been built and are in service. Based on nine reactances which have been calculated by the method under consideration and tested after final assembly of the transformers, the average of the ratio of calculated value to test value is 0.978; and one standard deviation from this average is only 0.0101. This is quite impressive, especially when it is considered that some of the error may be due to manufacturing tolerances and slight inaccuracies in test. Moreover, none of the transformer designs on which the method has been used is of the simplest type where standard equations provide us with sufficiently accurate results.

L. Rabins: I wish to thank Mr. Cogbill for his discussion and for the presentation of the data on production transformers. As he has stated, existing rigorous methods for reactance calculation were investigated. Calculations on the card-programmed calculator showed these to yield insufficiently accurate results so that the need for a less restrictive approach became apparent.

Flux Reversal in Magnetic Amplifier Cores

F. J. FRIEDLAENDER
ASSOCIATE MEMBER AIEE

IN RECENT years theun derstanding magnetic amplifier circuits has advanced rapidly, and great strides have been made in the art. However, it is recognized that several aspects of magnetic amplifier operation still need clarification. In most instances, the lack of a satisfactory explanation for certain circuit characteristics can be traced to an incomplete understanding of the behavior of the magnetic cores used. Therefore, a definite need exists for a study of the process of flux reversal in these magnetic amplifier components. The grain-oriented 50-per-cent nickel-iron alloys (such as Orthonol) are of particular interest and will be the material considered here. However, most of the results can probably be extended directly to other highly oriented "square hysteresis loop" materials.

A convenient starting point is found in an area in which considerable work has already been done, both experimentally and theoretically; namely, flux reversal under the influence of a step function of the magnetomotive force (mmf). This situation arises practically in many magnetic amplifier circuits and is closely approximated in magnetic amplifier applications with high control-circuit impedance. In the computer field similar situations are also encountered, though a less detailed knowledge of the process is usually required there.

The application of a step of mmf to a magnetic core, in addition to its practical importance, provides a forcing function comparatively easy to handle, both from a mathematical and an experimental point of view. As a basic procedure, the voltage induced in a separate pickup coil on the core has been observed upon application of a step of mmf, as done by previous experimenters.[1,2,3] Experimental evidence has been compared at all steps with theoretical considerations developed and modified as the work progressed. In the course of the study, conceptions expressed by physicists on the nature of ferromagnetism have been considered carefully; on the whole, however, the effort has been directed towards the development of an engineering model by engineering methods to meet immediate needs.

The model thus developed is utilized further as a basis for the study of other types of flux reversal, as occurring upon the application of other forcing functions, i.e., sinusoidal voltage. The ability of the model to account for these processes serves as a check on its usefulness.

Past Concepts of Flux Reversal in Tape Cores

The cores employed in magnetic amplifiers usually consist of a spiral of thin nickel-iron tape. It is convenient to begin an analysis of the magnetization processes in such cores by considering a single layer of the tape formed into a closed, circular cylinder with a radius r which is very large compared with the thickness d of the tape. A magnetic field is provided by a current flowing in an exciting winding placed toroidally on the tape. Then for a current of i amperes flowing in a winding of N turns, wound on a tape of length l centimeters where $l = 2\pi r$, considered constant over the cross section of the tape since $d << r$, the magnetic intensity at the tape is

$$\frac{Ni}{l}\ \frac{\text{ampere-turns}}{\text{centimeters}} = 0.4\pi \frac{Ni}{l}\ \text{oersted}$$

The voltage induced in a separate pickup coil, placed on the same tape core, has to be found as a function of time when a constant current I is suddenly applied to the exciting winding.

The original approach to the problem was to solve Maxwell's equations for the given geometry, with suitable assumptions about the B-versus-H relationship (i.e., the value of μ). If a linear B-versus-H relationship is assumed, an easily solved boundary value problem results.[4] However, it cannot be expected that such a treatment will give reasonably accurate predictions of the induced voltage (i.e., the rate of change of flux) during flux reversal for materials having very nonlinear B-versus-H relationships, such as a rectangular hysteresis loop. This approach may still be useful in predicting induced voltages occurring above the knee of a rectangular hysteresis loop in a saturated core.

It was recognized early that a realistic analysis would require careful consideration of the nonlinearities involved. Many approximate mathematical treatments were attempted. Among them are those considering a sectionally linear hysteresis loop. As a limiting case of such a loop, a rectangular B-versus-H relationship was assumed, ($\mu = \infty$ or $\mu = 0$) leading to a simpler mathematical formulation.

Wolman and Kaden[4] obtained the solution to this case, modified by the addition of a hysteresis term, with the use of the hysteresis loop of Fig. 1 under the following assumptions:

1. The entire tape is initially saturated.
2. Flux reversal takes place along a boundary of zero thickness.
3. Flux reversal starts in the two planes, represented by the large surfaces of the tape, and propagates into the material; see Fig. 2.
4. The value of H at the plane of flux reversal is equal to H_c, as required by the assumed hysteresis loop.

In this analysis, with a step of current I applied at $t=0$ resulting in a step of mmf denoted by F_k, the induced voltage per turn is found to be

$$\frac{e}{N} = -2w\sqrt{\frac{\rho H_s B_s}{0.4\pi t}}$$

where

$$H_s = 0.4\pi \frac{NI}{l} - H_c \qquad (1)$$

The time T_s required for flux reversal is also of interest. It is known as the switching time in the computer art

$$T_s = \frac{0.4\pi d^2}{4\rho H_s} \qquad (2)$$

More recently Papoulis[5] obtained essentially identical results to those of Wolman and Kaden[4] by more involved techniques for the solution of Maxwell's equations under the foregoing conditions.

Since the postulation of the modern theory of ferromagnetism by Pierre Weiss in 1907, it has been recognized that a ferromagnetic material consists of regions, known as domains, in which all the magnetic dipoles are aligned even without application of an external field.[6,7,8] In

Paper 56-219, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 20, 1955; made available for printing December 27, 1955.

F. J. FRIEDLAENDER is with Purdue University, Lafayette, Ind.

This work was performed in part under sponsorship of the United States Office of Naval Research. Portions of the paper were abstracted from a dissertation by F. J. Friedlaender, submitted to Carnegie Institute of Technology in partial fulfillment of the requirements for the degree of Doctor of Philosophy. The author gratefully acknowledges the advice and comments of Professors Leo A. Finzi and Jacob E. Goldman with the Ford Motor Company, and Howard M. McConnell, now with Jack and Heintz. Dr. L. J. Dijkstra, Westinghouse Research Laboratories, and Harold Lord, General Electric Research Laboratories, are thanked for their stimulating discussions of many aspects of the problem.

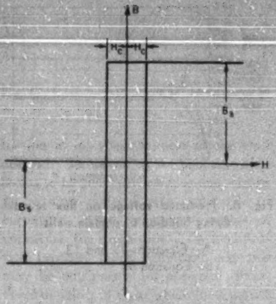

Fig. 1. Rectangular B-H loop for the limiting nonlinear analysis

grain-oriented materials, which exhibit rectangular hysteresis loops, nearly all the domains are known to be aligned parallel or antiparallel with the direction along which a field is normally impressed. On application of such a field, the boundary between oppositely oriented domains (known as a domain or Bloch wall) moves so that a growth of domains directed parallel to the applied field takes place. The motion of a domain wall under the influence of an external field is influenced by several factors.

1. Induced eddy currents reduce the field intensity available at the domain wall.

2. Damping effects other than those caused by eddy currents impede the motion of the wall. This type of damping is known as spin-relaxation damping.

3. The domain walls get caught by imperfections, inclusions, or inhomogeneities in the material, which contribute a frictional force-opposing wall motion, usually known as hysteresis.

4. Inertia effects may influence the acceleration of a domain wall.

5. The wall energy may be a factor influencing wall motion.

The physical principle which determines the formation and motion of Bloch walls is the minimization of the free energy of the system. But even in the idealized case of a single crystal of a ferromagnetic material, its general application is not practicable if a dynamic treatment with changing fluxes is considered. In addition, the nonuniform properties of commercial ferromagnetics on a nonmicroscopic scale makes it practically impossible to express all the forms of free energy mathematically, since they are mostly structure sensitive. For this reason, it is desirable to replace these more rigorous concepts with suitable engineering assumptions.

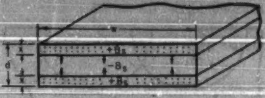

Fig. 2. Flux reversal in the limiting nonlinear analysis

It will be noted that the limiting nonlinear treatment of Wolman and Kaden[4] is completely equivalent to the assumption of an ideally oriented material, with the plane of flux reversal corresponding to a domain wall, though no reference is made to the physical process and only a B-versus-H relationship is postulated. Kittel, Williams, and Shockley[9] presented an analysis of the process of flux reversal in single crystals of silicon iron, based on their knowledge of the domain formations existing in this case. The geometrical arrangement of the test sample of Kittel, et al., differs from that considered here, but this does not detract from the importance of the results of those tests in relation to this study. Kittel, et al., consider first the application of a small magnetic intensity, barely exceeding the coercive force of the material. At such low H, it was found that the domain walls propagate as planar walls, their velocity being proportional to H_e, as defined in the foregoing. The authors show that this result can be predicted if the motion of the walls is assumed to be determined by "classical" eddy currents in the material. This corresponds precisely to the set of assumptions of Wolman and Kaden.[4] The results differ only in so far as the geometry differs. There is close agreement between experiment and theory.

The afore-mentioned limiting nonlinear treatments have been used with good results in the case of many materials and situations.[10] However, they fail in the case of most of the grain-oriented alloys used in magnetic amplifier applications.

A brief review of the literature discussed so far indicates that all the pertinent papers assume basically a planar surface separating oppositely oriented regions and moving from the entire surface of the tape toward its center. The motion is assumed to be determined by a volume distribution of eddy currents such that the value of H at the wall is equal to the coercive force H_c. The philosophy behind the assumption may differ in the papers, from those where even the term domain wall is not used to some of the more recent analyses in which the authors are able to advance very sound reasons in their situation for the existence of such planar domain walls.

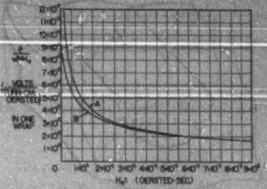

Fig. 3. Predicted induced voltage on flux reversal

A—Equation 1
B—Equation 4

Additional Considerations

The foregoing concepts of flux reversal fail to account for the behavior of grain-oriented nickel-iron alloys and other rectangular hysteresis loop materials under various conditions of flux reversal. Predictions of the induced voltage during flux reversal resulting from the application of a step of mmf F_k, as based on the foregoing concepts, yield the results shown in Fig. 3(A). However, the observed wave forms are as shown in Figs. 14 through 16. Also the effect of tape dimensions on the wave shape and on the numerical value of the time-to-saturation T_s does not agree with the predictions of the analyses quoted.

It is noted that the rate of change of flux (i.e., the switching voltage $e/N=-\dot{\phi}$) is not maximum at the time $t=0$ at which the step of mmf is applied, but reaches such a maximum after a fairly long fraction of the switching process. Recent discoveries in research on ferromagnetism suggest some direct modifications of the limiting nonlinear treatment:

1. The macroscopic or classical eddy currents are not the only damping factor influencing the motion of domain walls.

2. Higher order terms may also enter into the differential equation of motion of a domain wall; specifically, the possibility of an inertia effect in the wall motion should be considered.

3. A critical examination of the concept of a planar wall forming on the entire surfaces of the tape is required.

4. The shape of the moving domain walls may depart from the assumed planar wall.

The points 3 and 4 will form the subject of a detailed analysis in the following section, but points 1 and 2 can be used here in an attempt to improve on the existing treatment.

It is known[11,12] that there are several damping factors in addition to the macroscopic eddy currents considered so far.

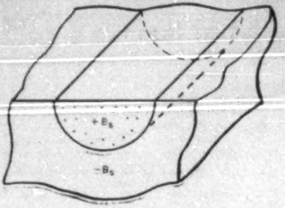

Fig. 4. Shape of an expanding domain

First of all, there are microscopic eddy currents which can be thought of as strictly local eddy currents, e.g., eddy currents of a local nature caused by the uneven motion of the wall around an inclusion or impurity, or as eddy currents taking place over the thickness of the domain wall which has been neglected so far. These currents differ from those already considered in that they depend only on the velocity of the wall (the rate of change of flux, or induced voltage) but not on the position of the wall in the tape since they are of a strictly local nature. There is a second damping factor which appears in the equation of motion of a Bloch wall in an identical manner as the afore-mentioned effect. It is known as spin-relaxation damping and seems to play an important role in the ferrites where eddy currents are practically nonexistent. In its effect spin-relaxation damping cannot be distinguished from the microscopic eddy-current effect in the process of flux reversal considered here.

The equation of motion of a domain wall under the influence of microscopic eddy currents and of the additional effects of microscopic eddy currents and spin-relaxation damping is written

$$\beta_e x\dot{x}+\beta_r\dot{x}=H_e \tag{3}$$

where $\beta_e=0.4\pi 2B_s/\rho$ and β_r is a constant depending both on spin relaxation and microscopic eddy currents.

The switching voltage per turn of pick-up coil becomes

$$\frac{e}{N}=-\dot{\phi}=\frac{-2wH_eB_s}{\sqrt{\frac{\beta_e}{2}H_et+\frac{(\beta_r)^2}{4}}} \tag{4}$$

and switching time

$$T_s=\frac{1}{H_e}\left(\frac{\beta_r}{2}d+\frac{\beta_e}{8}d^2\right) \tag{5}$$

By the inclusion of the term $\beta_r\dot{x}$, the initial switching voltage has been reduced to a finite value, but the wave shapes predicted by the new equation have not changed materially from those obtained previously; see Fig. 3(B).

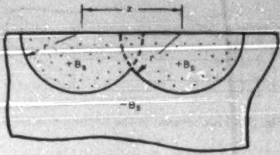

Fig. 5. Domain wall geometry after merging

It has been shown by Becker[13] that domain wall motion is also subject to an effect that appears like an inertia term in the equation of motion. The equation then becomes

$$m\ddot{x}+\beta_r\dot{x}+\beta_e x\dot{x}=H_e \tag{6}$$

The inertia term is thought to be very small, so that $m\ddot{x}$ can be neglected in most lower frequency applications. However, since the value of m could not be ascertained from the literature for the material considered, the possibility of a significant contribution of the inertia term to the process of flux reversal was also investigated. However, an attempt to correlate the foregoing differential equation with the experimentally observed wave forms of switching voltage showed that the equation does not describe the process even to a rough approximation. In the experimental part of this study, additional evidence will be introduced to show that the inertia term is insignificant in the magnetization processes discussed here, at least within the range of speeds of flux reversal considered.

Modified Concepts of Flux Reversal

Since the attempt to explain the process of flux reversal in grain-oriented ferromagnetics, 50-per-cent nickel-iron cores, by means of modification of existing models does not appear successful, a new model will now be formulated, which examines more critically the concept of domain wall formation.

So far it has been assumed that a surface of flux reversal, a domain wall, forms along the lateral sides of the tape and propagates inwards in planar form. Really the formation of regions of reverse magnetization may require considerable energy in an ideally oriented material in which all domain walls have been driven out previously by application of a large field in the opposite direction (i.e., the material is completely saturated). On the other hand, once a domain of reverse magnetization has been created at some point, flux reversal will proceed easily by a growth of this domain.

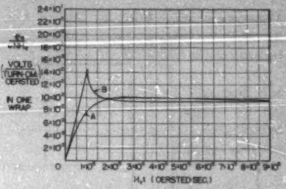

Fig. 6. Predicted voltage on flux reversal during build-up of domain walls

A—Equations 12 and 13
B—Equation 9

In practice, such an ideally saturated condition will not prevail. Judging from the nonperfect squareness of the top of a hysteresis loop it may be expected that upon removal of the saturating field intensity some "nuclei" (though only in a limited number) will be found which are not aligned with the other domains.

Such nuclei probably form around inclusions, impurities, and inhomogeneities (with associated Néel spikes and domains of closure),[14] mostly at the surface of the tape. Therefore, it will be assumed in the analysis that small regions exist near the surface of the tapes which contribute to the process of flux reversal, the tapes being considered having a thickness of 1 to 4 mils. Substantial experimental evidence in favor of such a hypothesis will be introduced later.

It is already clear that for an applied H smaller than the coercive H_c, none of the nuclei of reverse magnetization near or at the surface will grow; most flux changes that take place at such values of H can probably be attributed to departures from the idealized situation envisaged here, and they will be discussed subsequently. As H becomes larger than H_c, some of the nuclei will grow and, thus, cause flux reversal as the Bloch walls sweep over the entire tape. Increases in H are likely to cause more and more of these nuclei to grow. However, when H is large enough, further increases in H can only contribute to the rate of domain wall motion but can no longer add to the number of such walls which are causing flux reversal.

Most of the principles of domain wall motion have already been discussed in some detail and all that remains is to apply them to the situation envisaged here. The shape of the walls can hardly be expected to be planar, even at values of H barely in excess of H_c. For a domain wall with a curvature, the equation of

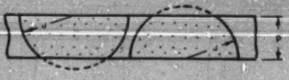

Fig. 7. Domain wall growth at low values of H

motion is modified because of the wall energy. However, this modification seems to be generally a minor one, except for extreme cases of very small radii of curvature. At a very small radius of curvature, the magnitude of the modification becomes more significant and this may be one reason for apparent differences in values of H_c at which the separate nuclei start to grow. In fact, the wall energy may be thought of as a substantial contributary factor to the value of H_c, and this will be discussed in more detail later.

Thus the equation of motion for a planar domain wall will still be retained. It takes the form of equation 3

$$\beta_r v+\beta_e g(x)v=H_e=0.4\pi\frac{NI}{l}-H_c \qquad (7)$$

where v is the velocity measured perpendicularly to the wall at any point. However, when domain wall motion takes place near the surface of the tape, the effect of the macroscopic eddy currents is small compared with that of the microscopic eddy currents and spin-relaxation damping which are independent of the wall position. Therefore, $\beta_e g(x)$ will be neglected altogether, until domain walls have penetrated 1 mil into the tape and have merged to form an essentially continuous wall.

According to some investigators,[15] the nuclei of reverse magnetization may most likely be of an ellipsoidal shape. In case of a thin tape having such regions located at the surface, long, cigar-shaped regions of reverse magnetization will be found intersecting the surface of the tape. Since the regions are long, they will be represented by circular cylinders interesecting the surface at a diameter. Any cross section of the tape will present a similar appearance. Hence, the subsequent motion of the domain walls is treated as a 2-dimensional problem; this approach appears to be a reasonable on-the-average description of the process.

Until adjacent domains merge, it is assumed that the semicircular configuration is preserved for the shape of the expanding domains; see Fig. 4. This assumption, which allows for welcome mathematical simplification, is consistent with the concept of minimization of domain wall energy.[16] No attempt is made to introduce specific assumptions about the initial radii of the semicylindrical nuclei at $t=0$ because of many effects discussed later; in fact, it shall be accepted that the radii are zero at $t=0$.

If a completely random distribution of nuclei in the 2-dimensional problem is assumed, the probability P_1 of finding a nucleus in the distance z is shown to be[17]

$$P_1=1-\epsilon^{-nz}$$

where n is the number of nuclei per centimeter.

The induced voltage per turn caused by two adjacent merging nuclei, Fig. 5, is

$$\frac{e_m}{N}=8B_s r\dot{r}\left(\frac{\pi}{2}-\cos^{-1}\frac{z}{2r}\right),\ 2r\geq z \qquad (8)$$

prior to merging $2r<z$, and $\cos^{-1} z/2r=0$. The expected induced voltage e_T is found by multiplying e_m by the probability density dP_1/dz and integrating over all z. Then the induced voltage per turn during flux reversal caused by one layer of tape is found to be[17]

$$\frac{e_T}{N}=Ax\int_0^{\pi/2}\epsilon^{-x\cos\theta}\,d\theta$$

$$=Ax\frac{\pi}{2}[I_0(x)-L_0(x)] \qquad (9)$$

where

$x=2nr$

$A=4wB_s\dot{r}$

$r\leq d/2$

$r=(H_e t)/\beta_r$

$\dot{r}=H_e/\beta_r$

I_0 = a modified Bessel function of zero order

L_0 = a modified Struve or Weber-Lommel function of zero order with imaginary argument, known as a Nicholson function

Equation 9 is plotted in Fig. 6(B). For tapes thicker than 2 mils, equation 4 applies after the domain walls have penetrated about 1 mil.

When the domain walls growing from opposite surfaces meet near the center of the tape and are annihilated, equation 9 no longer applies. This situation will be considered approximately only because of the mathematical complexities involved. At values of H barely in excess of H_c, there will be so few growing nuclei that most domain walls will not be annihilated till they reach the opposite surface; see Fig. 7. On the other hand, at large values of H, the annihilation of domain walls encountering other walls at the center of the tape may be approximated by placing an imaginary boundary along the center of the tape, Fig. 8, where annihilation of domain walls is assumed to occur at this boundary.

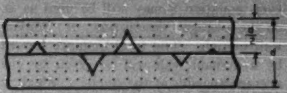

Fig. 8. Domain wall growth at large values of H

The resulting equations for the induced voltage e_{TD} per turn for small H

$$\frac{e_{TD}}{N}=\frac{e_T}{N}-Ax\cos^{-1}\frac{2dn}{x} \qquad (10)$$

for larger H

$$\frac{e_{TD}}{N}=\frac{e_T}{N}-Ax\cos^{-1}\frac{dn}{x} \qquad (11)$$

The previous analysis has been based on the assumption of a completely random distribution of growing nuclei. It may be of interest to carry out a similar analysis with the alternate assumption of an ordered distribution, i.e., the growing nuclei are assumed to be evenly spaced.

For this new case, the switching voltage prior to merging takes the value

$$\frac{e_T'}{N}=4B_s\pi r\dot{r}nw=\frac{\pi}{2}Ax \qquad (12)$$

where

$$2r\leq s=\frac{1}{n}$$

and the prime is used to denote the new case considered. After merging

$$2r>s$$

$$\frac{e_T'}{N}=4\pi rB_s w\sin^{-1}\frac{s}{2r}(2nr)\dot{r}=Ax\sin^{-1}\frac{1}{x} \qquad (13)$$

Here, e_T'/NA takes a maximum value of $\pi/2$ compared with that of about 1.096 for the random distribution of growing nuclei; see Fig. 6(A).

e_{TD}' is obtained from e_T' in the same manner as e_{TD} has been obtained from e_T in equations 10, and 11, i.e., by subtraction of a term $Ax\cos^{-1}2dn/x$, or ($Ax\cos^{-1}dn/x$). It will be observed that the expressions derived for e_T, e_{TD}, e_T', and e_{TD}' represent the domain wall area per unit length of tape in each case, as a function of time, if n and H_e and thus $\dot{r}$ are considered to be constants.

Influence of Core Dimension and H on T.

The time required for flux reversal or the switching time T_s will be considered for different ranges of values of H and core dimensions. At small values of H_e, very few nuclei will grow, and the wall motion will be quite nonuniform. How-linear capacitor. Here the peak stored linear capacitor is the average of the two half cycle cycle values. Of course, using the definitions for the loss factor D of a linear capacitor in terms of an equivalent series or parallel resistance, $D=R_s\omega C$ or $D=1/(R_p\omega C)$ respectively, the equivalent series or parallel resistances for the nonlinear capacitor can be calculated.

The equivalent capacitance and dissipation factor of the nonlinear capacitor were calculated for each loop. Figs. 9, 10, and 11 show these results. Fig. 9 displays the variation of the equivalent capacitance of the nonlinear capacitor with bias for various values of peak positive alternating voltage. For large values of alternating voltage, these curves show that the capacitance becomes nearly independent of bias. Thus, it is to be expected that the amplification of dielectric amplifier circuits in which the alternating voltage across the nonlinear capacitor is large will be less than that obtained with a smaller alternating voltage. These curves also show that, as the bias increases, the capacitance tends to become independent of the alternating voltage.

Fig. 10 demonstrates the latter point more clearly. Here equivalent capacitance is plotted against the peak positive alternating voltage for several values of bias voltage. For small values of bias voltage, the capacitance varies considerably with alternating voltage, but becomes nearly independent of alternating voltage for large bias voltages. Nonlinear resonance phenomena[7,8] will be less noticeable at high values of bias voltage than at low bias voltages.

In Fig. 11, the dissipation factor is plotted versus bias voltage for various peak positive alternating voltages. All of these curves show a trend of decreasing losses as the bias voltage is increased. This was evident upon examining the hysteresis loops, as the area of the loops decreased noticeably with increasing bias voltage, Figs. 7(A) and (B). These curves show that, for large values of bias higher values of resonant circuit Q are possible, which would tend to increase the amplification of a resonant dielectric amplifier.[1] Also, the temperature rise of the nonlinear capacitor will be less for a given energy input at high bias voltages.

Conclusion

The preceding representation of the nonlinear capacitor by equivalent linear elements simplifies analysis of the dielectric amplifier by making possible the application of linear circuit theory to circuits where the alternating voltage drop across the nonlinear capacitor is not small. Graphical methods can be applied to give solutions of the large signal properties and, by expressing the curves describing the behavior of the equivalent linear elements in terms of their partial derivatives about the quiescent point, the small signal properties can be analyzed in the same manner as vacuum-tube or transistor circuitry has been analyzed. Derivation of an equivalent circuit for the dielectric amplifier, determination of stability conditions, and optimization of circuit behavior are problems that are considerably reduced by this linear representation. Furthermore, the accurate prediction of resonant circuits where the Q is controlled by the nonlinear capacitor is now possible.

Discussion

E. A. Sack and **P. N. Wolfe** (Westinghouse Research Laboratories, Pittsburgh, Pa.): The authors of this paper have pointed out that the losses in the ferroelectric ceramic raised the temperature of their experimental specimen above the temperature of the silicone fluid. However, no information has been given as to the actual temperature of the ceramic at each point on the experimental curves. Without this information, both the data which have been presented and the conclusions the authors have drawn from them are strictly applicable only to the particular experimental configuration which was used.

At least two of the conclusions drawn by the authors are invalid when the hysteresis loops are studied at a constant ceramic temperature. First, when the ceramic temperature is maintained at a value slightly above the apparent Curie temperature, the hysteresis loops for a high-K ferroelectric are not accurately represented by straight lines. Second, under the same conditions, the major and minor loops actually do tend to nest, and the so-called mean polarization curve is a very reasonable approximation to the material behavior for use in computations where a single-valued representation is required.

The major hysteresis loops of Fig. 12 are for a high-K barium strontium titanate ceramic capacitor obtained from the same manufacturer as the material used by the authors. The peak of the applied alternating potential on the capacitor approached the maximum permitted by breakdown of the specimen. For the loops of Fig. 12(A), the specimen was suspended in a temperature-regulated silicone-fluid bath by a pair of thin wire leads. The more vertical loop was photographed immediately after the test voltage had been applied to the sample and the initial electric transient had subsided. Another exposure was made about 30 seconds later, at which time the loop had fallen over as shown. For Fig. 12(B), the sample was placed in an electrode structure which was specially designed to carry away the heat generated in the ceramic. This structure was immersed in the same silicone-fluid bath. Again, two exposures were made. This time, however, it can be seen that there was no significant change in the shape of the loop.

The results of the preceding test are in agreement with the conclusions of the authors in that the loops appear to fall over when the electrode structure is not adequate to maintain the ceramic temperature at the bath temperature. This test also shows that the special electrode structure used by us was adequate at the frequency used in the following tests.

Fig. 13 shows a nest of major hysteresis loops obtained at constant ceramic temperature. It can be seen that the smaller loops do not fall outside of the larger loops.

Fig. 12. Double exposures which show the effect of internal heating on the hysteresis loop of a ferroelectric ceramic

A—Inadequate cooling
B—Adequate cooling

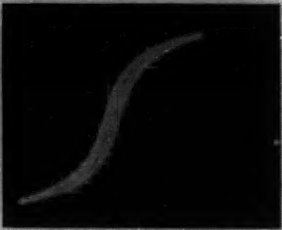

Fig. 13. Nest of major hysteresis loops for the ferroelectric ceramic

It should also be noted that the locus of the tips of the loops appear to be a far better approximation to the electrical behavior of the capacitor than a straight line.

Fig. 14 (A) is a minor loop for the ferroelectric ceramic capacitor. The direct bias on the ceramic for this loop was 300 volts and the alternating potential swing was 580 volts, zero to peak. In Fig. 14(B) this same loop has been photographed through the (photographic) negative of a major loop formed by an alternating voltage which reached the same negative peak value. It is apparent that the minor loop lies within the major loop and does not, as the authors contend, fall far outside of this boundary.

Fig. 15 is a minor loop for the same bias, but with a 427-volt zero-to-peak alternating-potential swing applied to the capacitor. Again, this loop lies within the major loop. Similar photographs have been made for a wide range of bias and alternating voltages. In no case do the minor loops deviate significantly from the path of the major loop locus.

Finally, Fig. 16(A) shows the area covered by a very large number of minor loops. This figure is compared with the major dynamic loop for the same maximum potential swing. The congruence of the two figures is readily apparent.

The preceding tests emphasize the importance of either maintaining or measuring the actual ceramic temperature when taking data concerning the hysteresis loops of the ferroelectric dielectric. These tests also indicate that, when the ceramic temperature is constant, the mean polarization curve is a more accurate single-valued approximation to the electrical behavior of the material than the straight lines proposed by the authors. Finally, the tests show that it is highly desirable to provide an adequate cooling structure for the ferroelectric capacitors in a dielectric amplifier, since the nonlinearity and, therefore, the control capabilities of the ceramic are diminished by severe internal heating.

Fig. 14. Minor loop for an alternating potential of 580 volts zero to peak and a direct bias of 300 volts

A—Minor loop
B—Same loop photographed through the (photographic) negative of a major loop

In closing, it should be stressed that we do not claim that the data and conclusions presented by the authors are incorrect for the specific experimental configuration which they have examined. We do contend, however, that since the authors did not know the temperature of the ceramic in their tests, their conclusions must not be interpreted as generalizations and are valid only for one particular thermal geometry.

Earl Wingrove, Louis Depian, and **W. Lee Shevel:** We wish to thank Mr. Sack and Mr. Wolfe for their discussion, but find that the conditions used by them are not those ordinarily encountered in practical dielectric amplifiers. The object of the paper is to show a representation of the nonlinear capacitor when used in typical dielectric amplifier circuitry. There is little use to discuss the capacitor behavior in conditions foreign to such circuitry. The goal of the amplifier is to provide a device which has certain desirable characteristics, such as reasonably high-voltage gain, acceptable bandwidth, good stability, and reasonable operating temperature. The bandwidth depends upon the carrier frequency used. It has been shown (see ref. 7 of the paper) that, with carriers of the order of 1 megacycle, a frequency response flat to 10 kc is possible. We used a carrier of about 0.6 megacycle at which the bandwidth was 4 to 5 kc. Operation of a dielectric amplifier at carrier frequencies below, say 15 kc, may not be considered too practical. From a temperature point of view, a convenient operation would be with an ambient of room temperature. We used an ambient of 30 degrees centigrade. The discussers, using the same material, maintained the temperature slightly above the Curie temperature (12 degrees centigrade). Examining the loops of this paper and those of the discussers, it can be seen that the loops at 30 degrees centigrade are very linear compared to the loops at about the Curie temperature. It is apparent that the discussers' objection to the linear representation is valid only in that particular case of operation near the Curie temperature.

Mr. Sack and Mr. Wolfe do not mention the frequency at which their curves were obtained. This is unfortunate since we found that an adequate electrode structure is indeed easily obtainable at low carrier frequencies. This, of course, will allow the nesting of the hysteresis loops, as shown by the discussers and in the paper; see Fig. 4. However, at more useful higher frequencies of 0.5 megacycle, such an electrode structure is not too practical and if then the temperature of the bath is kept constant, the loops will fall over as shown in the paper. Furthermore, under normal operating conditions, it can be shown that because of the low heat conductivity of the material, the temperature of the center of the ceramic may be higher (10 degrees centigrade is not uncommon) than that of the silvered surface. Therefore, the temperature of the ceramic is not necessarily constant even if this is accomplished for the silvered surface through large electrodes.

Another point is also of interest. Using a singled-valued representation such as the mean polarization curve, as the discussors suggest, and representing the losses by some constant independent of bias or peak alternating voltage, there is no way of taking into account the variation of losses of the capacitor. With the loop interpretation as given in the paper, this is done and the losses are found as a function of bias and peak alternating voltage. The dielectric amplifier under the operating conditions stated in the paper yielded a stable voltage gain of 15 which is significantly higher than that reported in the literature to date.

Power Transistor Switching Circuit

CHAANG HUANG
NONMEMBER AIEE

EDWIN SLOBODZINSKI
NONMEMBER AIEE

TO STUDY power transistor switching circuits, it is necessary to measure relevant d-c transistor parameters as functions of current and temperature. Based on the measured results, design methods can be developed for high-power bistable switching circuits which have good trigger sensitivity and d-c stability over wide temperature ranges.

Among the d-c transistor parameters, the most temperature-dependent parameter is the reverse collector current. If the operating voltage is quite small compared to the breakdown voltage, the reverse collector current is composed of two parts:

1. A leakage current I_{cl} which varies linearly with the applied voltage, and which is relatively independent of temperature.
2. A temperature-sensitive but voltage-independent component I_{ct}.

When the ambient temperature is raised, the temperature-sensitive component of the reverse collector current will increase in an exponential fashion. This current flows in the base region of the transistor and produces a transversal voltage drop which tends to bias the center of the emitter forward.[1] When a certain temperature is reached, the emitter will start to inject minority carriers and the collector current will be increased, resulting in an increase in power dissipation and junction temperature. The increase in junction temperature will further increase the reverse collector current and, consequently, increase the transversal voltage drop and emitter injection. This is a cumula-effect. It causes an OFF switching transistor to turn ON without the application of a triggering pulse. A means of compensating for this instability is to use a suitable base bias to prevent the emitter from injecting carriers. An excessive base bias, on the other hand, will not allow the switching transistor to have a stable ON state.

It is the purpose of this paper to describe the methods and results of the measurements of the d-c parameters of a *2N68* power transistor. With these data, several power transistor switching circuits are considered with an emphasis on the design of the base bias for temperature considerations. These design techniques can be easily adopted to permit their application to most direct-coupled switching circuits with the use of p-n-p or n-p-n transistors.

Measurement of Parameters

The d-c equivalent circuit of a transistor is shown in Fig. 1.

Where

r_e, r_b, r_c = d-c emitter, base, and collector resistances respectively
I_{ct} = temperature-sensitive component of the reverse collector current
α = the large signal or d-c amplification factor

α is defined as[2]

$$\alpha = \frac{I_c(V_c, V_e) - I_c(V_c, 0)}{I_e(V_c, V_e)} \qquad (1)$$

The measurement of r_e is made by passing a forward current through the emitter base circuit with the collector terminal open-circuited. If a high impedance voltmeter is connected across the collector emitter terminals, the voltage read is essentially $I_e r_e$. With I_e measured, r_e is determined as a function of the forward current.

The values of r_e versus I_e of a *2N68* power transistor are plotted in Fig. 2. The emitter resistance takes a high value when the emitter current is in the reverse direction. This value is of minor importance in the design of power transistor circuits.

Similarly, if a forward current is passed through the emitter base circuit, the voltage read across the collector base terminals determines r_b as a function of forward base current, as shown in Fig. 3.

When the emitter is biased in the reverse direction, the emitter current is near to zero. The voltage distribution caused by the flow of the reverse base current appears between the emitter and base terminals. This voltage is dependent on the magnitude of the reverse base current. The effect of this voltage on circuit performance can be lumped into an apparent base resistance r_b, defined as the ratio of the emitter-base voltage to the reverse base current. The variations of r_b versus the reverse base current for different values of ambient temperature are plotted in Fig. 4.

To measure the r_c, the reverse collector characteristic is first obtained, as shown in Fig. 5. The reverse collector current can be written as

$$I_{c0} = I_{ct} + \frac{V_c}{r_c}$$

Thus

$$r_c = \frac{dV_c}{dI_{c0}}$$

A plot of r_c versus V_c is given in Fig. 6. The variation in I_{c0} with junction temperature at a given collector bias is illustrated in Fig. 7.

The large-signal current-amplification factor α can be measured with either d-c or pulse methods. The collector is placed at a specified voltage while the emitter current is increased from zero to a certain value I_e. The ratio of the change in the collector current from I_{c0} to the value of I_e is, by definition, the d-c amplification factor at emitter current I_e and collector voltage V_c. Fig. 8 shows the variation of α versus I_e.

Power Transistor Flip-Flop Circuit Design

A conventional p-n-p junction transistor flip-flop circuit is shown in Fig. 9 with a compensating base bias indicated by R_b and E_{bb}. First consider the OFF transistor (transistor *T-1* in Fig. 9). Temperature compensation is required to keep this transistor OFF. Fig. 10 is a simplified diagram of the OFF transistor circuit, where the current generator

$$\frac{E_{cc}}{R_{1c} + R_{2f} + r_{2b}}$$

represents the current fed to the base of the ON transistor. $E_{c,ON}$ is the ON transistor's collector voltage (the saturation collector voltage of the ON transistor no. 2). To keep transistor *T-1* in the OFF state, it is required that

$$I_{1e} < 0$$

or

$$I_{1b} \leq I_{1c}$$

Circuit analysis, Appendix I, leads to the requirement that

$$R_{1b} \leq \frac{E_{bb}R_{1f} - r_{1b}(T)I_{c0}(T)R_{1f}}{I_{c0}(T)(r_{1b}(T) + R_{1f}) + E_{c,ON}} \qquad (2)$$

where

T = temperature
I_{c0} and r_b = the temperature-dependent parameters

Paper 56-251, recommended by the AIEE Electronics Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 20, 1955; made available for printing January 16, 1956.

CHAANG HUANG is with Sylvania Electric Products, Inc., Woburn, Mass., and EDWIN SLOBODZINSKI is with the International Business Machines Corporation, Poughkeepsie, N. Y.

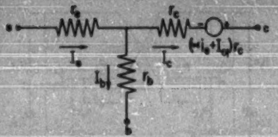

Fig. 1. Transistor d-c equivalent circuit

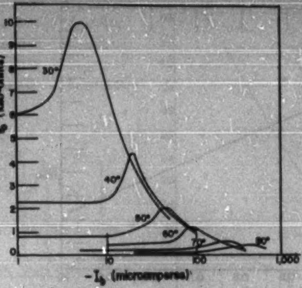

Fig. 4 (above). r_b versus I_b

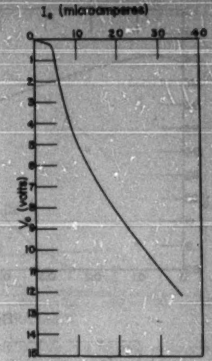

Fig. 5 (right). V_c—I_e characteristic

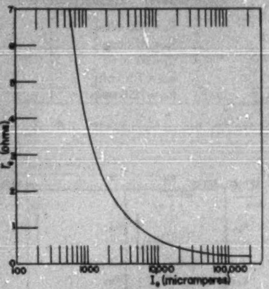

Fig. 2. Forward r_e versus I_e

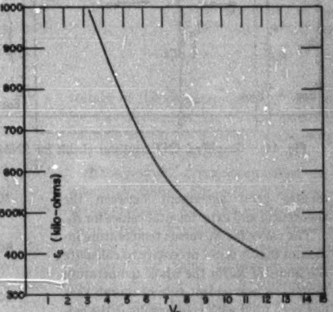

Fig. 6 (right). r_c versus V_c

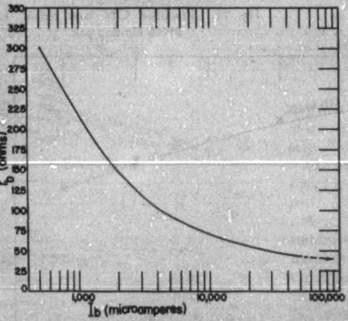

Fig. 3. Reverse r_b versus I_b

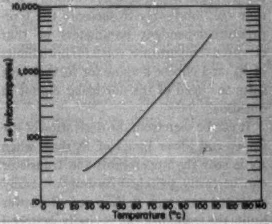

Fig. 7. I_{co} versus temperature at 12 volts

which thus places an upper limit on R_b.

Next consider the requirements for transistor *T-1* to be in the ON state and obtain a lower limit for R_{1b}. A simplified ON transistor circuit is shown in Fig. 11. This circuit was drawn, assuming that the ON i_e r_e drop is very small compared with the i_b r_b drop.

For a transistor to be in the ON state, its collector current has to be saturated

$$I_{1c}=\frac{E_{cc}}{R_{1c}}\leq\frac{\alpha_1}{1-\alpha_1}I_{1b} \tag{3}$$

where α_1 is the d-c amplification factor.

Circuit analysis, Appendix I, leads to lower limit for R_{1b}

$$R_{1b}\geqq\frac{(R_{1f}+R_{1c})[\beta_1 R_{1c}E_{bb}+r_{1b}(T)E_c]}{E_c[\beta_1 R_{1c}+R_{1f}+R_{2c}+r_{1b}(T)]} \tag{4}$$

where

$$\beta_1=\frac{\alpha_1}{1-\alpha_1}$$

Similarly

$$\frac{(R_{2f}+R_{2c})[\beta_2 R_{2c}E_{bb}+r_{2b}(T)E_{cc}]}{E_{cc}[\beta_2 R_{2c}+R_{2f}+R_{2c}+r_{2b}(T)]}\leq R_{2b}\leq \frac{E_{bb}R_{2f}-R_{2f}r_{2b}(T)I_{c0}(T)}{I_{c0}(T)(r_{2b}(T)+R_{2f})+E_{c,\text{ON}}}$$

To illustrate the design procedure, a sample symmetrical flip-flop circuit is designed. If $E_{cc}=12$ volts, $E_{bb}=7.5$ volts and $I_{c,\text{ON}}\doteq 1.2$ amperes, then $R_c=10$ ohms, with $\beta\doteq 10$, and $i_b\doteq 120$ milliamperes.

The consideration for R_f is that it should provide sufficient feedback current while not causing an excessive drop in the OFF transistors collector load; i.e.

$$R_e\leq R_f\leq\frac{E_c}{I_b}-(R_c+r_b)$$

Here the values of R_f are 50 ohms.

Substituting these values and the temperature-dependent parameters of the transistor into equations 2 and 4, the upper and lower limits of permissible R_b are obtained, which are plotted and compared with the experimental upper limit of R_b in Fig. 12. The comparison in-

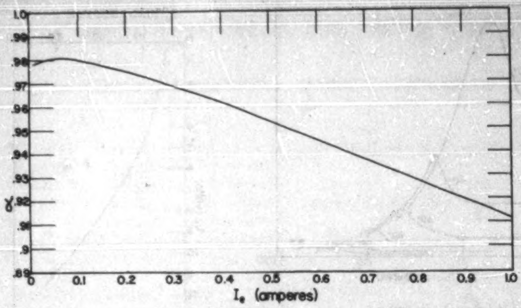

Fig. 8. α versus I_e

dicates good agreement between the theoretical and experimental values for R_b.

The curve for R_b versus temperature indicates that it is not necessary to calculate the limits of R_b for the whole temperature range. A convenient rule of thumb that has been used with good results is the calculation of R_b for the maximum junction temperature which is to be realized. It is now only necessary to measure the temperature-dependent parameters at that elevated temperature, solve for both limits of R_b, and choose a value for R_b that best suits the need of the particular circuit in question.

It can be seen from the derivation of the upper and lower limits of R_b that, when R_b is near the upper limit the transistor can be easily switched ON but not easily switched OFF, and, if R_b is near the lower limit, the transistor can be easily switched OFF but not easily switched ON. For optimum trigger sensitivity, sometimes it is favorable to use a temperature-sensitive element,[3] the resistance of which lies between the two limits.

It is to be noted that, in the expression for the lower limit of R_b, the d-c amplification factor β is actually temperature-dependent. But the variation is found to be small. For a conservative design, a value of R_b should be used which is higher than the lower limit of R_b that was calculated with the assumption that α was constant.

2N34 Flip-Flop Circuit with Cascaded Power Transistors

The power transistor circuit described in the foregoing was found to possess relatively poor trigger sensitivity. In other words, relatively large triggering power is required. Fig. 13 shows a circuit with a much improved trigger-sensitivity characteristic. This circuit consists of two *2N34* transistors in a flip-flop circuit driving two cascaded *2N68* transistors, resulting in an output current of 1 ampere.

Following the same temperature considerations, $i_e<0$ for the OFF transistors and $I_b>E_c/(R_c\beta)$ for the ON transistors. A circuit analysis, Appendix II, yields criteria for the choice of base bias resistances, which are listed in the following equations.

$$\frac{E_{2bb}+I_{4b}r_{4b}+I_{3b}r_{3b}+(E_{2cc}-I_{4b}r_{4b}-I_{3b}r_{3b})\,\frac{r_{2b}}{R_{2c}\beta_2}}{\frac{E_{1cc}-I_{4b}r_{4b}-I_{3b}r_{3b}}{R_{2f}+R_{1c}}-\frac{E_{2cc}-I_{4b}r_{4b}-I_{3b}r_{3b}}{R_{2c}\beta_2}\left(1+\frac{r_{2b}}{R_{2f}+R_{1c}}\right)} \qquad (5)$$

$$\frac{E_{3bb}-E_{4bb}}{I_{3c0}}+R_{4b}-r_{3b}>R_{3b}>\frac{E_{3cc}+I_{4b}r_{4b}+\left(\frac{E_{3cc}-I_{4b}r_{4b}}{R'_{c}\beta_3}\right)r_{3b}}{\frac{E_{3bb}-I_{4b}r_{4b}}{R_{3c}}-\left(1+\frac{r_{3b}}{R_{3c}}\right)\left(\frac{E_{3cc}-I_{4b}r_{4b}}{R_{3c}\beta_3}\right)}$$

$$\frac{E_{4bb}}{I_{4c0}(T+\Delta T)}-r_{4b}(T+\Delta T)>R_{4b}>\frac{\frac{E_{4cc}r_{4b}}{R_{4c}\beta_4}+E_{4bb}}{\frac{E_{3cc}}{R_{3c}}-\frac{E_{4cc}}{R_{4c}\beta_4}\left(1+\frac{r_{4b}}{R_{3c}}\right)}$$

where

$$I_{4b}=\frac{\frac{E_{3cc}}{R_{3c}}-\frac{E_{4bb}}{R_{4b}}}{1+\frac{r_{4b}}{R_{4b}}+\frac{r_{4b}}{R_{3c}}}$$

and

$$I_{3b}=\frac{\frac{E_{2cc}-I_{4b}r_{4b}}{R_{2c}}-\frac{E_{3bb}+I_{4b}r_{4b}}{R_{3b}}}{1+\frac{r_{3b}}{R_{2b}}+\frac{r_{3b}}{R_{3b}}}$$

To insure d-c stability for an ambient temperature range of 25 to 80 degrees centigrade, the circuit parameters were chosen so that the upper limits of the base load resistance would not intersect their corresponding lower limit in the desired temperature range. In the design of a circuit of this type, the detailed considerations to be made are as follows:

The circuit parameters of *T-4* are designed to produce the desired output current. The values of R_{3c} and R_{3c} are to be chosen while keeping in mind that emitters of *T-3* and *T-2* are at finite negative voltages when the transistors are in the ON state, these negative voltages being the successive $I_b r_b$ drops. The choice of E_{3bb} and E_{2bb} are not as random as is the choice of E_{4bb}. They must be chosen to compensate for the positive emitter voltage of the OFF transistors as well as for the increase of I_{c0}. These positive voltages appear as a result of the successive positive base biases.

In the case of *T-2* there is an added consideration; namely, the feedback loop consisting of R_{2f} and R_{1c}. The upper limit of R_{2b} is strongly dependent on R_{2f} whereas R_{1c} has a minimum value dependent on the maximum value allowable on collector current for *T-1*. A compromise must be made providing sufficient feedback while still limiting the ON collector current of *T-1*.

With the properly chosen parameters in the circuit of Fig. 13 for an output of 1 ampere and 12 volts, the upper limits of R_{4b}, R_{3b}, R_{2b}, and R_{1b} are plotted in Fig. 14 as curves *a*, *b*, *c*, and *d*, respectively. The minimum values of R_{4b}, R_{3b}, R_{2b}, and R_{1b} are 50 ohms, 1,000 ohms, 3,600 ohms, and

13,480 ohms respectively. In the foregoing calculation the final value of the base-biasing resistors were chosen so that the trigger sensitivity would be good while a change in transistor parameters would not result in unstable operation.

With the requirement of R_b versus temperature fairly well understood, the entire design procedure may be simplified. Since the upper limits of R_b, R_{2b}, and R_{3b} decrease with temperature, it is simply a matter of measuring the relevant temperature-dependent parameters at the maximum required temperature of operation, solving for the limits of R_b at that temperature, and making a choice of values to suit the needs of the circuit in question. In the case of R_{3b} it may be necessary to plot the curve of the upper limit so that unstable operation at low temperatures may be avoided. In all cases, each particular application may require different considerations. However, the basic method remains the same.

2N34-2N68 Transistor Flip-Flop Circuit with Cascaded Power Transistor

The circuit described previously may be simplified by the deletion of one *2N34*. This consists of a *2N34-2N68* flip-flop circuit with the *2N68* cascaded to another *2N68* power transistor, as shown in Fig. 15.

The temperature consideration of requiring $I_c<0$ for each OFF transistor and $I_b>E_{cc}/(R_c\beta)$ for each ON transistor leads to the design criteria shown in the following; see Appendix III

$$\frac{E_{1bb}R_{1f}-I_{1co}r_{1b}R_{1f}}{E_{2c,\mathrm{ON}}+I_{1co}R_{1f}+r_{1b}I_{1co}}>R_{1b}>$$

$$\frac{\left(E_{1bb}+\dfrac{E_{1cc}r_{1b}}{R_{1c}\beta_1}\right)(R_{1f}+R_{2c})}{E_{2cc}-\dfrac{E_{1cc}}{R_{1c}\beta_1}(R_{1f}+R_{2c}+r_{1b})}$$

$$\frac{R_{2f}(E_{2bb}-E_{3bb}+I_{3co}R_{3b}-I_{2co}r_{2b})}{E_{1c,\mathrm{ON}}+E_{3bb}+I_{2co}r_{2b}-I_{3co}R_{b3}+I_{2co}R_{2f}}>R_{2b}>$$

$$\frac{E_{2bb}+I_{3b}r_{3b}+(E_{2cc}-I_{3b}r_{3b})\dfrac{r_{2b}}{R_{2c}\beta_2}}{\dfrac{E_{1cc}-I_{3b}r_{3b}}{R_{2f}+R_{1c}}-\dfrac{E_{2cc}-I_{3b}r_{3b}}{R_{2c}\beta_2}\left(1+\dfrac{r_{2b}}{R_{2f}+R_{1c}}\right)} \tag{6}$$

$$\frac{E_{3bb}}{I_{3co}(T+\Delta T)}-r_{3b}(T+\Delta T)>R_{3b}>$$

$$\frac{\dfrac{E_{3cc}r_{3b}}{R_{3c}\beta_3}+E_{3bb}}{\dfrac{E_{2cc}}{R_{2c}}-\dfrac{E_{3cc}}{R_{3c}\beta_3}\left(1+\dfrac{r_{3b}}{R_{3c}}\right)}$$

The same considerations enter into the calculations for the base-biasing resistors as described in the previous case. The upper limits of R_{3b}, R_{2b} and R_{1b} are plotted in Fig. 16 as curves *a*, *b*, and *c* respectively. The lower limits of R_b remain essentially constant with temperature.

From the behavior of the R_b curves of Fig. 16, it is again evident that the temperature-dependent parameters need only to be measured at the maximum operating temperature required. Solving for the upper and lower limits of R_b at this temperature provides a range of values of permissible R_b. The choice of R_b depends on the particular circuit requirements.

Trigger Sensitivity

The trigger sensitivities of the three circuits described were measured and compared in Fig. 17. The improvements in required amplitude and width of the trigger pulse are obvious from this comparison. The fact that d-c coupling was used in the circuits of improved trigger sensitivity does not mean to exclude the possibility of capacitive or inductive coupling. However, the trigger-sensitivity characteristic of the *2N68* flip-flop circuit indicates the need for a driver to supply a large, wide pulse. Although the widening of pulse width can be achieved by using monostable circuits, or the like, coupling this pulse to the low base input impedance is highly impractical.

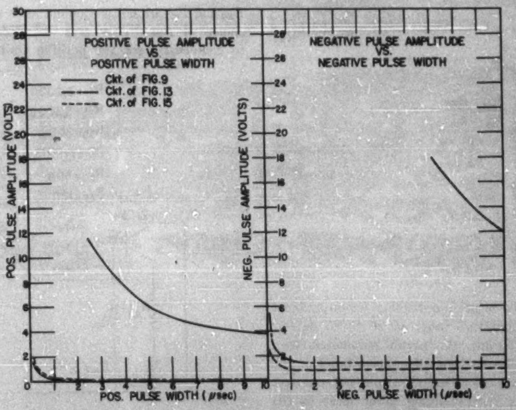

Fig. 17. Comparison of trigger sensitivities

Conclusion

The parameters of germanium transistors are known to be temperature-dependent. The effect of the temperature dependence of the transistor parameters on bistable power transistor circuits has been studied and a technique was developed to compensate for these effects. Based upon this technique, high-power bistable circuits have been designed to operate at elevated ambient temperatures with good d-c stability and trigger sensitivity. From the study it was found that the parameters most influencing stable operation of germanium transistors over wide temperature ranges are the d-c base resistance r_b, the saturation collector current I_{c0}, and the large signal amplification factor α.

Appendix I. Circuit Analysis

Upper Limit for R$_{1b}$ (Fig. 10)

When the transistor is in the OFF state, the emitter current and junction voltage are both near zero. By assuming the voltage across Ae to be zero, the following loop equations are obtained

$$I_{1b}\left(r_{1b}+\frac{R_{1b}R_{1f}}{R_{1b}+R_{1f}}\right)=\frac{-E_{bb}R_{1f}-E_{c,ON}R_{1b}}{R_{1b}+R_{1f}}$$

$$I_{1c}(r_{1c}+R_{1c})=E_{cc}+I_{c1}r_{1c}-\frac{E_{cc}R_{1c}}{R_{1c}+R_{2f}+r_2}$$

since

$$r_{1c}>>R_{1c},\ I_{c0}=I_{c1}+\frac{E_{cc}}{r_c}$$

and

$$\frac{E_{c,ON}}{r_{1c}}+I_{c0}>>\frac{E_{cc}R_{1c}}{(R_{1c}+R_{2f}+r_{2b})r_{1c}}$$

The condition $-I_b\geq I_c$ leads to equation 2.

Lower Limit for R$_{1b}$ (Fig. 11)

The loop equations are as given in the following:

$$E_{bb}=I_{f1}R_{1b}-I_{1b}(r_{1b}+R_{1b})$$

$$I_{1f}R_{f1}+(I_{2c0}+I_{1f})R_{2c}=E_{cc}I_{1b}r_{1b}$$

By assuming $I_{2c0}R_{2c}<<E_{cc}$ and solving for I_{1b},

$$I_{1b}=\frac{E_{cc}R_{1b}-E_{bb}(R_{1f}+R_{2c})}{r_{1b}R_{1b}+(r_{1b}+R_{1b})(R_{1f}+R_{2c})}$$

For $I_{c,ON}$ to be saturated

$$I_{1b}\geq\frac{E_c}{R_{1c}}\,\frac{1-\alpha}{\alpha}$$

Solving for R_{1b} and letting $\alpha/(1-\alpha)=\beta$, equation 4 is obtained.

Appendix II. Deviation of Upper and Lower Limits of the Base Resistances for a Pair of Flip-Flop Transistors with Two Cascaded Transistors (Fig. 13)

The limits for R_{1b} are the same as in Appendix I.

Upper Limits for R$_{2b}$ to Keep T-2 OFF

When *T-2* is OFF, the emitter current is very small; the base current is essentially the reverse collector current I_{2c0}. At the same time *T-3* is OFF and *T-1* is ON, the emitter voltage of *T-2* is $E_{3bb}-I_{3c0}R_{3b}$, while the collector voltage of *T-1* is $E_{1c,ON}$ (the saturation voltage of *T-1*).

By making use of the Thevenin's theorem, the base voltage of *T-2* can be shown to be

$$\frac{E_{2bb}R_{2f}}{R_{2b}+R_{2f}}-\frac{E_{1c,ON}R_{2b}}{R_{2b}+R_{2f}}-I_{2c,ON}\frac{R_{2b}R_{2f}}{R_{2b}+R_{2f}}$$

Thus, the voltage at the internal junction of *T-2* is

$$\frac{E_{2bb}E_{2f}}{R_{2b}+R_{2f}}-\frac{E_{1c,ON}R_{2b}}{R_{2b}+R_{2f}}-I_{2c,ON}\frac{R_{2b}R_{2f}}{R_{2b}+R_{2f}}-I_{2c0}r_{2b}$$

To keep *T-2* OFF, this voltage is required to be more positive than the emitter voltage of *T-2*, $(E_{3bb}-I_{3c0}R_{3b})$.

$$R_{2b}<\frac{R_{2f}(E_{2bb}-E_{3bb}+I_{3c0}R_{3b}-I_{2c0}r_{2b})}{E_{1c,ON}+E_{3bb}+I_{2c0}r_{2b}-I_{3c0}R_{3b}+I_{2c0}R_{2f}}$$

Lower Limit of R$_{2b}$ to Keep T-2 ON

When *T-2* is ON, *T-3* and *T-4* are both ON while *T-4* is OFF. The base voltage of *T-2* is, therefore $(I_{4b}r_{4b}+I_{3b}r_{3b}+I_{2b}r_{2b})$.

Thus, the current flowing through R_{2b} is

$$\frac{E_{2bb}+I_{4b}r_{4b}+I_{3b}r_{3b}+I_{2b}r_{2b}}{R_{2b}}$$

and the current flowing through R_{2f} is

$$\frac{E_{1cc}-I_{4b}r_{4b}-I_{3b}r_{3b}-I_{2b}r_{2b}}{R_{2f}+R_{1c}}$$

Consequently, the base current of *T-2* is

$$I_{2b}=\frac{E_{1cc}-I_{4b}r_{4b}-I_{3b}r_{3b}-I_{2b}r_{2b}}{R_{2f}+R_{1c}}-\frac{E_{2bb}+I_{4b}r_{4b}+I_{3b}r_{3b}+I_{2b}r_{2b}}{R_{2b}}$$

Solving for I_{2b}

$$I_{2b}=\frac{R_{2b}(E_{1cc}-I_{4b}r_{4b}-I_{3b}r_{3b})-(R_{2f}+R_{1c})(E_{2bb}+I_{4b}r_{4b}+I_{3b}r_{3b})}{[R_{2b}(R_{2f}+R_{1c})]+r_{2b}(R_{2f}+R_{1c}+R_{2b})}$$

Since the emitter voltage of *T-2* is $-(I_{4b}r_{4b}+I_{3b}r_{3b})$, the collector current of *T-2* is

$$I_{2c}=\frac{E_{2cc}-I_{4b}r_{4b}-I_{3b}r_{3b}}{R_{2c}}$$

To keep *T-2* ON, it is required that

$$I_{2b}>\frac{I_{2c}}{\beta_2}$$

Substituting and rearranging of term lead to the following equation:

$$R_{2b}>\left[\frac{E_{2bb}+I_{4b}r_{4b}+I_{3b}r_{3b}+(E_{2cc}-I_{4b}r_{4b}-I_{3b}r_{3b})\dfrac{r_{2b}}{R_{2c}\beta_2}}{\dfrac{E_{1cc}-I_{4b}r_{4b}-I_{3b}r_{3b}}{R_{2f}+R_{1c}}-\dfrac{E_{2cc}I_{4b}r_{4b}-I_{3b}r_{3b}}{R_{2c}\beta_2}\left(1+\dfrac{r_{2b}}{R_{2f}+R_{1c}}\right)}\right]$$

Upper Limit for R$_{3b}$ to Keep T-3 OFF

When *T-3* is OFF, *T-4* is also OFF. The internal junction voltage of *T-3*, $E_{3bb}-I_{3c0}(R_{3b}+r_{3b})$, is required to be more positive than the emitter voltage of *T-3*, $(E_{4bb}-I_{4c0}R_{4b})$.

Thus

$$R_{3b}<\frac{E_{3bb}-E_{4bb}}{I_{3c0}}+R_{4b}+r_{3b}$$

Lower Limit for R$_{3b}$ to Keep T-3 ON

Similar to the considerations described in the section entitled "Lower Limit of R_{2b} to Keep *T-2* ON," the base current of *T-3* can be derived to be

$$I_{3b}=\frac{R_{3b}(E_{2cc}-I_{4b}r_{4b})-R_{3c}(E_{3bb}+I_{4b}r_{4b})}{R_{3b}R_{3c}+r_{3b}(R_{3b}+R_{3c})}$$

and the collector current is

$$I_{3c}=\frac{E_{3cc}-I_{4b}r_{4b}}{R_{3c}}$$

Requiring $I_{3b}>I_{3c}/\beta_3$ and rearranging terms

$$R_{3b}>\left[\frac{E_{3bb}+I_{4b}r_{4b}+\left(\dfrac{E_{3cc}-I_{4b}r_{4b}}{R_{3c}\quad\beta_3}\right)r_{3b}}{\dfrac{E_{2cc}-I_{4b}}{R_{3c}}-\left(1+\dfrac{r_{3b}}{R_{3c}}\right)\dfrac{E_{3cc}-I_{4b}r_{4b}}{R_{3c}\beta_3}}\right]$$

Upper Limit for R$_{4b}$ to Keep T-4 OFF

When *T-4* is ON, its junction temperature is assumed to be ΔT higher than the ambient temperature. Immediately after *T-4* is turned OFF, the junction temperature will remain at $T+\Delta T$, where T is the ambient temperature. The internal junction voltage is $E_{4bb}-I_{4c0}(T+\Delta T)R_{4b}+r_{4b}(T+\Delta T)$ and the emitter voltage is zero. To keep *T-4* OFF, the internal junction voltage is required to be more positive than the emitter voltage, thus

$$R_{4b}<\frac{E_{4bb}}{I_{4c0}(T+\Delta T)}-r_{4b}(T+\Delta T)$$

Lower Limit for R$_{4b}$ to Keep T-4 ON

Similar to the considerations described in the section entitled "Upper Limits for R_{2b} to Keep *T-2* OFF," the base current of *T-4* can be shown to be

$$I_{4b}=\frac{R_{4b}E_{3cc}-R_{3c}E_{4bb}}{R_{4b}R_{3c}+r_{4b}(R_{3c}+R_{4b})}$$

and the collector current is as in the following:

$$I_{4c}=\frac{E_{4cc}}{R_{4c}}$$

Requiring $I_{4b}>I_{4c}/\beta_4$

$$R_{4b}>\left[\frac{\dfrac{E_{4cc}}{R_{4c}\beta_4}r_{4b}+E_{4bb}}{\dfrac{E_{3cc}}{R_{3c}}-\dfrac{E_{4cc}}{R_{4c}\beta_4}\left(1+\dfrac{r_{4b}}{R_{3c}}\right)}\right]$$

Appendix III. Derivation of the Upper and Lower Limits of the Base Resistance for a Pair of Flip-Flop Transistors with One Cascaded Transistor (Fig. 15)

This is a special case of Appendix II. As *T-4* is nonexistent, *I* etc. *R* etc. *r* etc. 0. Substituting these into the inequalities listed in equation 5 obtains those of equation 6. Note that *T-2* is a *2N68* power transistor in one case and a *2N34* in the other.

Analysis of Instability and Response of Reactors with Rectangular Hysteresis Loop Core Material in Series with Capacitors

JALAL T. SALIHI
STUDENT MEMBER AIEE

Synopsis: An exact analysis is given for a reactor having an idealized magnetization characteristic consisting of two linear regions of zero inductance, interrupted by a linear region of infinite inductance, when connected in series with a load comprising of capacitance and resistance under the action of a sinusoidal applied voltage. The recent developments in core materials have introduced magnetic materials such as Deltamax* and Orthonol† which have magnetization characteristic, at high values of saturation, approximating the ideal case. Thus the results obtained on the basis of an idealized analysis show good correlation with practical results obtained by experimenting on Deltamax cores. The circuit analyzed is the simplest circuit exhibiting an unstable and multivalued behavior attributed by several authors to a nonlinear resonance, sometimes referred to as ferroresonance phenomenon. Since the ideal magnetization characteristic assumed, consisting of regions of zero and infinite inductance, could not resonate with the finite load capacitance, the behavior of the circuit is explained by a different approach.

Analyzing the circuit on the basis of conduction angle is a new approach to the treatment of the problem. Thus a set of equations are obtained which are solved and expressed graphically. The co-ordinates of the curves are suitably chosen so that a single set of universal characteristics for different values of the phase angle of the load may be applied to any reactor, regardless of size or frequency, provided that the material of the core has magnetization characteristics similar to that of Deltamax. The multivalued behavior of the circuit and the degree of instability are determined by the charging rate of the capacitor which is controlled by the amount of resistance and capacitance present in the circuit. An explanation of the behavior of the circuit based on the effect of capacitor charge is given.

THE wide application of cores with rectangular hysteresis loop has increased the demand for an analysis of the behavior of such cores under the action of sinusoidal applied voltages. The behavior is similar in some respects to that of a gas tube. The similarity lies in the fact that the current for a given applied voltage flows only for a portion of the cycle, and is practically negligible outside this range. The conduction angle reduces with a reduction in the value of the voltage, reaching zero at a certain voltage called the critical voltage, beyond which the reactor ceases conducting. However, the relationship between conduction angle and applied voltage is quite different from that of a gas tube. It is controlled by two factors. the critical value of the flux density, at which the core saturates, and the nature of the load. In references 1 and 2 the behavior of such a reactor for cases of both pure resistance loads, and inductance-plus-resistance loads are investigated. For each case an analytical expression relating the conduction angle and applied voltage was deduced. The critical voltage at which the core starts firing is the same, regardless of the type of load. The firing angle characteristic is different for different loads. This difference becomes evident in the behavior of the circuit after firing. This may be seen in Fig. 1, where E_c represents the critical firing voltage and curves *a*, *b*, and *c* represent typical characteristics for the cases of resistive, inductive and capacitive loading respectively.

Nomenclature

A = effective core area (measured area × stacking factor of the core material) cm^2
B_c = critical value of flux density, gausses
C = load capacitance, farads
e = instantaneous value of applied voltage, volts
E = rms value of applied voltage, volts
E_c = critical value of rms applied voltage at which firing takes place, volts
E_c' = critical value of rms applied volts at which extinction takes place, volts
i = instantaneous value of current, amperes
I_{avg} = average value of current during half-cycle, amperes
N = number of turns of reactor winding
R_L = load resistance, ohms
R_w = resistance of reactor winding, ohms
R = effective resistance $R=R_L+R_w$, ohms
v = instantaneous value of voltage across capacitor, volts
V = voltage across capacitor during saturation, volts

q = instantaneous value of capacitor charge coulombs

Q = condenser charge during saturation, coulombs

α_f = angle for a positive half-cycle of the a-c supply voltage wave at which firing occurs, degrees or radians

α_c = angle for a positive half-cycle of the a-c supply voltage wave through which conduction is maintained, degrees or radians

α_{cc} = critical conduction angle corresponding to E_c, degrees or radians

α_{cc}' = critical conduction angle corresponding to E_c', degrees or radians

B = instantaneous value of flux density, gausses

ϕ = phase angle $= \tan^{-1}\dfrac{1}{\omega CR} = \tan^{-1}\dfrac{1}{\omega C(R_L+R_w)}$, degrees or radians

ϕ_c = critical value of phase angle where for $\phi<\phi_c$ the circuit does not exhibit unstable behavior, degrees or radians

Φ = total flux, lines

ω = angular velocity of supply voltage, radians per second

Curve *a* in Fig. 1 for the case of resistive loading is independent of the value of resistance, while curve *b* represents only one curve of a family corresponding to different values of $\phi=\tan^{-1}R/\omega L$ showing that the addition of inductance to the load will increase the conduction angle for the same applied voltage, thus making the reactor more sensitive to changes in voltage. Curve *c*, for the case of capacitive loading, represents only one of a family of curves corresponding to different values of $\phi=\tan^{-1} 1/\omega CR$ showing that for voltages ranging from $E_c'<E<E_c$ there is more than one possible mode of operation, depending on whether the voltage is increasing or decreasing. Thus starting from zero, if the voltage is increased the reactor does not conduct until the critical voltage E_c is reached, after which the operation point suddenly jumps to the point P_1. For further increase in voltage the conduction angle increases smoothly along the curve up to some point P_2. If the voltage is then reduced, the conduction angle reduces in the same manner down to the point P_1, where the voltage is again equal to E_c. A further reduction in voltage is described by the region P_1P_3 along which the conduction angle reduces smoothly to the point P_3, which corresponds to a second critical point at which a further reduction in voltage desaturates the core abruptly. This interesting nonlinear phenomenon associated with the case of capacitive loading is referred to in literature as the phenomenon of ferroresonance. It is important from theoretical and practical consideration and is made use of in control and computer circuits.

Investigations of the circuit treated in this paper but of different magnetization characteristic were made by several authors. The critical points were deduced either by graphical methods,[3] or from knowledge of the behavior of one reactor by applying the principle of similitude,[4] or by fitting certain equations to measured relations.[5] For the idealized magnetization characteristic assumed in this paper, exact mathematical relations are derived describing the behavior of the circuit for all ranges of operation including the critical points.

Theory and Assumptions

The experimental circuit consists of a nonlinear reactor with Deltamax core of magnetization characteristic shown in Fig. 2, connected to a 60-cycle-per-second (cps) variable voltage source in series, with a load consisting of the load resistance R_L and a capacitance C. The equivalent circuit is shown in Fig. 3, where the resistance of the reactor is lumped with the load. The design details of the reactor are given in Fig. 4.

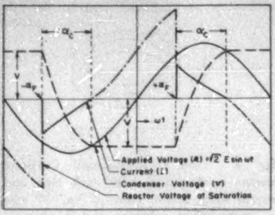

Fig. 6. Shapes and relative phases of applied voltage, current, capacitor voltage, and voltage across reactor for basic circuit of Fig. 3

Because of the particular shape of magnetization characteristic, the reactor behaves like a gas tube conducting only for a certain angle through which the core saturates, while the current outside this range is practically negligible. The validity of this assumption improves with an increase in the value of the saturation current. This condition is fulfilled in most practical applications. Thus, for the purpose of analysis, an idealized magnetization characteristic of Fig. 5 is assumed, which is equivalent to the following assumptions:

1. The current outside conduction range is zero.
2. The voltage across the capacitor during the nonconducting intervals remains constant. This follows from assumption 1, since the charge on a capacitor cannot change unless current flows.
3. The inductance of the core at saturation is zero.
4. Hysteresis and eddy current losses are negligible.

It is further assumed that the distributed and the winding capacitances of the reactor are negligible, as is the leakage of the load capacitor.

Analysis of Circuit

The wave shapes of current flowing in the circuit and the voltage across the capacitor will reveal some important relationships, shown in Fig. 6, where e represents the instantaneous value of the applied voltage. The origin of time is conveniently chosen so as to start from the initiation of a positive voltage wave. The instantaneous current, i flows only through the interval of time corresponding to the conduction angle α_c, and is zero outside the conduction interval because of the infinite inductance associated with the ideal reactor assumed. Thus, during nonconduction intervals, the instantaneous voltage v across the capacitor remains constant, provided the self-leakage of the capacitor is negligible. This is true since a change in voltage across the capacitor should be associated with a current flow which could only take place during the conduction intervals, during which the voltage across the capacitor reverses its polarity. Furthermore it may be concluded that, due to symmetry and periodicity of the applied voltage, the magnitude of the constant voltage V, across the capacitor during the nonconduction intervals corresponding to a positive pulse of the applied voltage, is equal to the magnitude of the constant voltage across the capacitor during the nonconduction intervals corresponding to negative pulses of the applied voltage. However, the polarity of these voltages is different. To justify the validity of these ideal assumptions to practical cases, typical oscillograms of the current wave shape and the corresponding voltage across the capacitor are shown in Fig. 7.

The magnitude of the constant voltage across the capacitor during nonconducting intervals may be calculated easily by making use of the fact that at $\omega t=\alpha_f+\alpha_c$, the current, i is zero. This may be seen in Fig. 6, which necessitates the condition that the voltage across the capacitor at this instant should be equal to the instantaneous value of the applied voltage, i.e.,

$$V=\sqrt{2}E\sin(\alpha_f+\alpha_c) \tag{1}$$

The behavior of the circuit may be represented by two differential equations describing the operation of the circuit during presaturation and saturation intervals. The differential equation corresponding to presaturation region is of the form

$$N\frac{d\Phi}{dt}\times 10^{-8}=V+\sqrt{2}E\sin\omega t \tag{2}$$

where the voltage drop across the resistance is assumed to be zero, and the constant voltage across the capacitor is substituted by an equivalent d-c source in series with the applied voltage.

During the saturation interval, the voltage drop across both resistance and capacitor must be accounted for while the voltage drop associated with the inductance of the reactor is zero. Thus the equation describing the operation of the circuit is of the form

$$Ri+\frac{1}{C}\int i\,dt=\sqrt{2}E\sin\omega t \tag{3}$$

These two equations give enough information to solve the circuit by a proper choice of the boundary conditions so as to fit the solutions together at the transition intervals between the two regions.

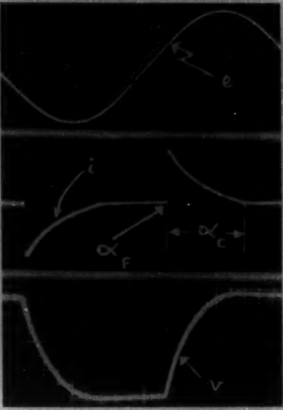

Fig. 7. Oscillograms of applied voltage, current, and capacitor voltage for experimental reactor of Fig. 4, C=1 microfarad, ϕ=70 degrees, E=100 volts, f=60 cps

It is important to point out that a relationship between applied voltage and average load current could not be expressed in a direct form. However, both these quantities could be expressed in terms of the conduction angle; thus an indirect relationship may be obtained. This is the reason for using the conduction angle as the basis for analysis.

Discussion of Relationships Derived

RELATIONSHIP BETWEEN FIRING ANGLE AND CONDUCTION ANGLE

The relationship between firing angle and conducting angle is derived in Appendix I, as equation 11, and is of the form

$$\alpha_f=\tan^{-1}\times\left(\frac{\sin\phi-\sec\phi\sin\alpha_c-\sin(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}{\sec\phi-\cos\phi+\sec\phi\cos\alpha_c+\cos(\alpha_c+\phi)\times\epsilon^{+\alpha_c\times\tan\phi}}\right) \tag{4}$$

showing that this relationship for a fixed $\phi=\tan^{-1}1/\omega CR$ is independent of the size of the reactor. That is, for two reactors of different sizes independently loaded, provided the phase angle in both cases is made equal by adjusting the loads and the conduction angles are made equal by adjusting the applied voltages, the firing angle will be the same for both cases.

RELATIONSHIP BETWEEN APPLIED VOLTAGE AND CONDUCTION ANGLE

The relationship between applied voltage and conduction angle is derived in Appendix II as equation 13 and is of the form

$$\frac{E}{AB_cN\omega}=\frac{\sqrt{2}}{10^8}\times\left(\frac{1}{(\pi-\alpha_c)\sin(\alpha_f+\alpha_c)-\cos\alpha_f-\cos(\alpha_f+\alpha_c)}\right) \quad (5)$$

where $E/AB_cN\omega$ is expressed as a function of both firing and conduction angles. This form of the relationship is more suitable for the purpose of calculation than the next expression, which is a function of α_c alone. This may be obtained by substituting equation 4 in equation 5 as shown in Appendix II, and the expression derived is of the form

$$\frac{E}{AB_cN\omega}=\frac{\sqrt{2}}{10^8}\left\{\frac{\sec\phi\times\tan^{-1}\left(\dfrac{\sin\phi-\sec\phi\sin\alpha_c-\sin(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}{\sec\phi-\cos\phi+\sec\phi\cos\alpha_c+\cos(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}\right)}{[(\pi-\alpha_c)\sin\alpha_c-\cos\alpha_c-1]+[(\pi-\alpha_c)\cos\alpha_c+\sin\alpha_c]\left(\dfrac{\sin\phi-\sec\phi\sin\alpha_c-\sin(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}{\sec\phi-\cos\phi+\sec\phi\cos\alpha_c+\cos(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}\right)}\right\} \quad (6)$$

From this it may be concluded that the relationship between $E/AB_cN\omega$ and the conduction angle α_c for a fixed value of $\phi=\tan^{-1} 1/\omega CR$, is independent of the size of the reactor; i.e., $E/AB_cN\omega$ should be equal for both of the two reactors of different sizes which are independently loaded, provided the conduction angle in both cases is made equal by adjusting the applied voltages.

RELATIONSHIP BETWEEN AVERAGE VALUE OF LOAD CURRENT AND CONDUCTION ANGLE

The relationship between average value of load current and oonduction angle is derived in Appendix III and of the form

$$\frac{RI_{avg}}{AB_cN\omega}=\left(\frac{2\sqrt{2}\cot\phi}{\pi}\right)\left(\frac{E}{AB_cN\omega}\right)\sin(\alpha_f+\alpha_c)=\frac{4\cot\phi}{\pi\times10^8}\left(\frac{\sin(\alpha_f+\alpha_c)}{(\pi-\alpha_c)\sin(\alpha_f+\alpha_c)-\cos\alpha_f-\cos(\alpha_f+\alpha_c)}\right) \quad (7)$$

where $RI_{avg}/AB_cN\omega$ is expressed as a function of both firing and conduction angle. This form of the relationship is more suitable for the purpose of calculation than the next expression, which is a function of α_c alone, obtained by substituting equation 4 in equation 7. This is shown in Appendix III, and the expression derived is of the form

$$\frac{RI_{avg}}{AB_cN\omega}=\frac{4\cot\phi}{\pi\times10^8}\left\{\frac{\sin\alpha_c+\cos\alpha_c\left(\dfrac{\sin\phi-\sec\phi\sin\alpha_c-\sin(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}{\sec\phi-\cos\phi+\sec\phi\cos\alpha_c+\cos(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}\right)}{[(\pi-\alpha_c)\sin\alpha_c-\cos\alpha_c-1]+[(\pi-\alpha_c)\cos\alpha_c+\sin\alpha_c]\left[\dfrac{\sin\phi-\sec\phi\sin\alpha_c-\sin(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}{\sec\phi-\cos\phi+\sec\phi\cos\alpha_c+\cos(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}\right]}\right\} \quad (8)$$

From which it may be concluded that the relationship between $RI_{avg}/AB_cN\omega$ and the conduction angle α_c for a fixed value of $\phi=\tan^{-1}$ $(1/\omega cR)$ is also independent of the size of the reactor.

RELATIONSHIP BETWEEN APPLIED VOLTAGE AND LOAD CURRENT

A direct relationship between rms applied voltage E and the average load current I_{avg} could not be obtained. However for any value of ϕ the corresponding values of $E/AB_cN\omega$ and $RI_{avg}/AB_cN\omega$ may be calculated by using equations 6 and 8. Thus, an indirect relationship between $RI/AB_cN\omega$ and $E/AB_cN\omega$ may be tabulated and expressed graphically. Furthermore, since both of these quantities for a given phase angle are independent of the size of the reactor, it follows that the relationship between them is also independent of the size of the reactor.

The fact that all the relationships derived are expressed in nondimensional form suggests a practical set of characteristics for different assumed values of phase angle ϕ. Calculation of these characteristics can be tedious because of the long equations involved; however, considerable time is saved if the following steps are taken, assuming any fixed value of ϕ:

1. From equation 4 find values of firing angle α_f, corresponding to different values of conduction angle α_c.
2. If values of α_c and the corresponding values of α_f are substituted in equation 1, values of $V/\sqrt{2}E$, corresponding to different values of α_c may be calculated.
3. If values of α_c and the corresponding values of α_f are substituted in equation 5, values of $E/AB_cN\omega$, corresponding to different values of α_c may be calculated.
4. Similarly, with the use of equation 7, values of $RI_{avg}/AB_cN\omega$ corresponding to different values of α_c may be calculated.
5. If the results obtained from steps 3 and 4 are tabulated, values of $RI_{avg}/AB_cN\omega$ corresponding to different values of $E/AB_cN\omega$ may be obtained.

Fixing values of ϕ at 10, 20, 30, 40, 50, 60, 70, and 80 degrees, this procedure was followed for each case. The calculated characteristics are expressed graphically in Figs. 8, 9, 10, 11, and 12.

Fig. 8 represents the relationship between firing angle and conduction angle, showing that as the load is made more capacitive, then for the same conduction angle, the corresponding firing angle is reduced. The straight line $\phi=0$ corresponds to the case of pure resistive load where $\alpha_f=180-\alpha_c$.

Fig. 9 shows the manner in which the constant voltage V across the capacitor during presaturation intervals expressed as a fraction of the maximum value $\sqrt{2}$ E of the sinusoidal applied voltage varies with conduction angle. The conduction angle varies as a result of the variation in applied voltage, as will be discussed next; thus, if the applied voltage is varied both V and α_c change while the relationship between $V/\sqrt{2}\ E$ and α_c is described by the curves of Fig. 9. A study of these curves is essential to explain the reason for instability; furthermore it will be shown that the degree of instability is related to the shape of these curves. For a fixed ϕ, as the conduction angle is increased due to an increase in applied voltage, V approaches nearer to the maximum value of the applied voltage; for example when $\phi=80$ degrees, $V/\sqrt{2}\ E$ is 0.76 and 0.98, corresponding to conduction angles of 30 and 60 degrees respectively. It may also be concluded that for a constant conduction angle, $V/\sqrt{2}\ E$ is larger for larger values of ϕ.

Figs. 10(A) and (B) show the variation of conduction angle with the nondimensional applied voltage $E/AB_cN\omega$, where $1/AB_cN\omega$ at a fixed frequency is a constant for a given reactor. When the voltage is gradually increased from zero, the reactor does not fire until a critical voltage E_c is reached. E_c is the value of E which satisfies the condition $E/AB_cN\omega=0.77\times10^{-8}$.

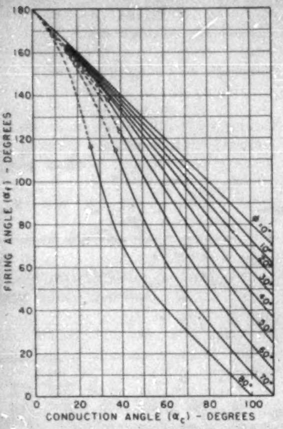

Fig. 8 (left). Calculated relationship between firing angle and conduction angle

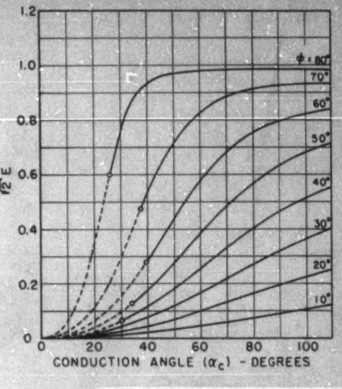

Fig. 9 (right). Calculated relationship between conduction angle and constant voltage across capacitor during presaturation intervals, expressed as a fraction of the maximum applied voltage

Figs. 11(A) and (B) show the variation of the nondimensional average current $RI_{avg}/AB_cN\omega$ with conduction angle, where $R=R_L+R_w$ is the effective resistance of the circuit.

Figs. 12(A) and (B) relate the average load current to applied voltage in a nondimensional form very convenient for practical application. In the range shown in Fig. 12(B) the relationship is remarkably linear.

In all the characteristics discussed the dashed lines correspond to negative resistance associated with unstable operation. The negative resistance is absent in those curves corresponding to $\phi<\phi_c$, where ϕ_c is a critical value for the phase angle.

Practical Application of Relationships Derived

The nondimensional set of characteristics given are determined by values of phase angle $\phi=\tan^{-1} 1/\omega CR$ assumed, while the effect of core size, winding details, the value of critical flux density, the frequency of supply, the applied voltage, the effective resistance, and the current flowing may be grouped and thought of as single factors $E/AB_cN\omega$ or $RI_{avg}/AB_cN\omega$, which do not change the shape but simply correspond to certain operating points on the characteristics; consequently they are applicable to any reactor size having Deltamax cores or any future cores which might be developed of similar character where the presaturation current is negligible. The characteristics are applicable at any such reasonably low frequency that the basic assumptions made are not violated.

To apply the characteristics to practical cases it is first necessary to know the value of $1/AB_cN\omega$, which at a fixed frequency is constant for a given reactor. This constant may be found either by calculation if design details are provided, or by measurements. Figs. 10(A) and 12(A) indicate that the critical firing voltage E_c is theoretically independent of the load and is given by that value of E at which $E/AB_cN\omega=0.77\times10^{-6}$. Thus $1/AB_cN\omega=0.707\times10^{-6}/E_c$ may easily be measured by a voltmeter connected across the applied voltage which is increased slowly up to the critical value at which firing takes place. The firing action may be noticed from observation of current oscillograms or by noting the sudden current rise in an ammeter connected in series with the load. Tests performed on the experimental reactor of Fig. 4 show that the values of $\phi<\phi_c$, where the circuit does not exhibit unstable modes, E_c is practically independent of the load condition as predicted theoretically, while for $\phi>\phi_c$, there is a slight reduction in the value of E_c, the deviation increases as ϕ is increased reaching 3 per cent for $\phi=80$ degrees. Thus for accurate measurement of E_c the phase angle should be less than ϕ_c or simply a pure resistive load may be chosen.

As a practical example, consider the reactor of Fig. 4 connected to a 60-cps 100-volt source, in series with a capacitor of 1 microfarad and a resistance of 820 ohms, which makes the effective resistance of the circuit $R=R_L+R_W=820+145=965$ ohms. It is required to find the average current, the conduction angle, and the firing angle.

The first step is to find the constants for the given reactor; thus a variable voltage was applied to the circuit while the capacitor was short-circuited so as to make the load resistive. The critical firing voltage measured was 43 volts; making use of this the constants are

$$\frac{1}{AB_cN\omega}=\frac{0.707\times10^{-6}}{43}=0.0164\times10^{-6}$$

$$\frac{R}{AB_cN\omega}=965\times0.0164\times10^{-6}=15.8\times10^{-6}$$

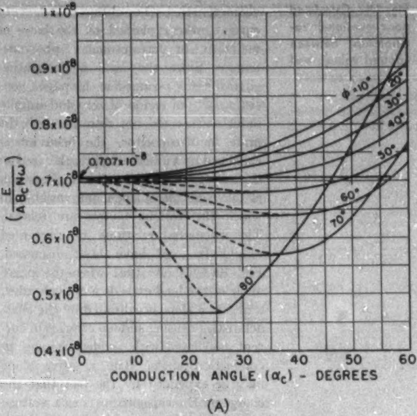
$$\phi=\tan^{-1}\frac{1}{\omega CR}=\tan^{-1}\frac{10^6}{2\pi\times60\times965}=70°$$

Now, for an applied voltage of 100 volts $E/AB_cN\omega=100\times0.0164\times10^{-6}=1.64\times10^{-6}$. The corresponding nondimensional average current is 0.50×10^{-6}, obtained from the characteristics of Fig. 12(B); thus $I_{avg}=0.50/10^6\times AB_cN\omega/R=0.50/15.8=0.0316$ ampere.

To obtain the conduction angle, use Fig. 10(B), from which $\alpha_c=91.5$ degrees. With this value of conduction angle the firing angle may be obtained from Fig. 8 from which $\alpha_f=21$ degrees.

The corresponding results obtained by direct measurements on the oscillograms of Fig. 7, are about 0.033 ampere, 95 degrees, and 23 degrees respectively.

To check the validity of the assumptions made in this paper a wider range of measurements was made on the experimental reactor. Fig. 13 shows a comparison of the calculated values of the average load current with experimental results, showing good correlation. Five widely different values of phase angle were chosen; in each case the applied voltage was varied and the corresponding average load current was obtained from measurement of oscillogram areas. The slight difference between measured and calculated results, the former being higher, is due to the flow of presaturation current



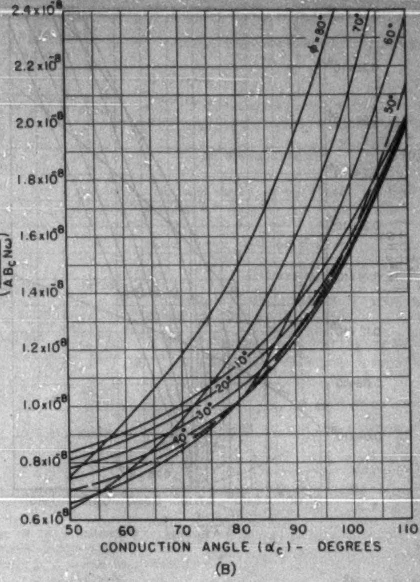


Fig. 10 (above). Calculated nondimensional relationship between applied voltage and conduction angle

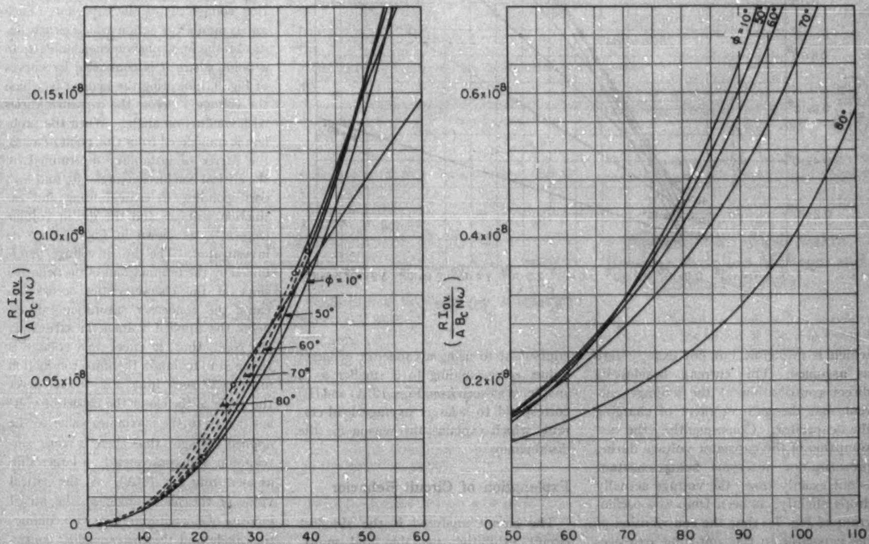
Fig. 11 (below and right). Calculated nondimensional relationship between average current and conduction angle



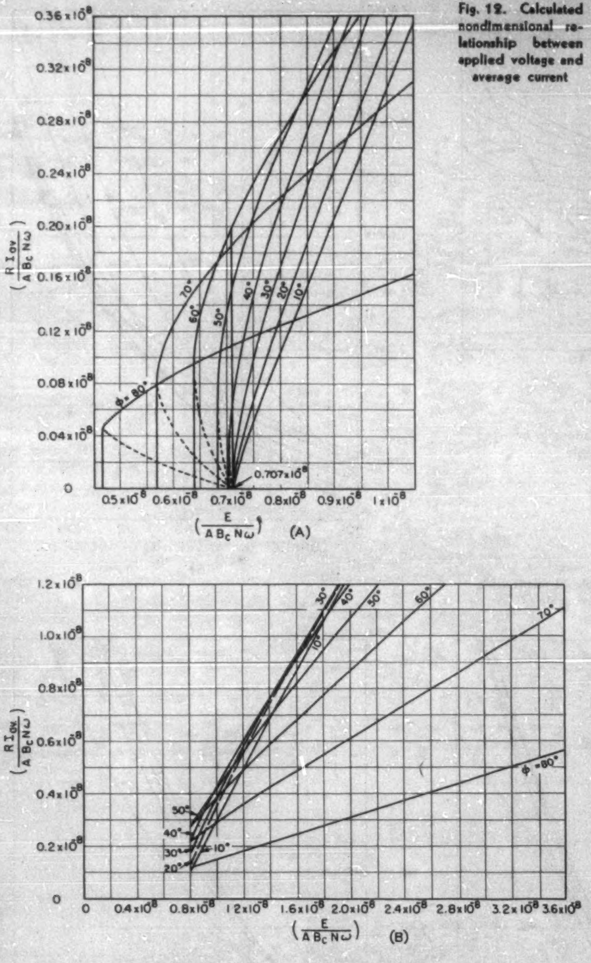


Fig. 12. Calculated nondimensional relationship between applied voltage and average current

which is negligible but not exactly zero as assumed. This current, besides its direct contribution to the average current, has the indirect effect of charging the capacitor. Consequently, the assumption of the capacitor voltage during presaturation intervals being constant is not exactly true; the voltage actually drops slightly, as seen from the oscillogram of Fig. 7; thus the contribution of the capacitor to the volt-time area necessary to raise the flux is slightly less than the theoretical case. This is roughly equivalent to using a capacitor of larger value, corresponding to a smaller ϕ; a smaller ϕ as seen from Figs. 12(A) and (B) correspond to a larger average load current, which explains the reason for the discrepancy.

Explanation of Circuit Behavior

The circuit analyzed is the simplest circuit exhibiting unstable and multivalued behavior. In analyzing the same circuit but with different magnetization characteristics, the abrupt changes of current were explained on the basis of nonlinear or ferroresonance phenomenon.[5,6] Since the ideal magnetization characteristic assumed in this paper, consisting only of region of zero and infinite inductance, could not resonate with the finite load capacitor, the behavior is explained by a different approach based on the variation of conduction angle, which is taken as an independent variable to which the various factors are related. The calculated relations are presented graphically and have been discussed. Fig. 10(A) shows that when the phase angle of the load exceeds a critical value, a negative slope is exhibited by the characteristics causing sudden changes in current associated with sudden changes in conduction angle. The negative slope may be explained by the fact that the charge on the capacitor acts as a voltage source helping the applied voltage to saturate the core. Thus at the instant when the critical firing voltage is just exceeded, the reactor fires and the capacitor is charged. The constant voltage V across the capacitor during presaturation intervals, Fig. 6, in helping the applied voltage will reduce the presaturation intervals; consequently, the conduction intervals are increased. The increase in conduction angle causes more current to flow which in turn raises the presaturation voltage across the capacitor. Such an accumulative action which clearly indicates the jump phenomenon builds up to a point where it is controlled by curves of Fig. 9, indicating the manner in which the voltage V across the capacitor varies with conduction angle. When the problem is considered from this point of view, the degree of instability determined by the critical conduction angles α_{cc} and α_{cc}', corresponding to critical firing and extinction voltages and the dip in voltage $(E_c - E_c')$, as shown in Fig. 1, may be investigated. The dip in voltage determined by the terminations of the negative slope of the characteristics occurs because the condenser saturation voltage helps the applied voltage in saturating the core; thus, in effect, less voltage is required to maintain the same conduction angle. As seen from Fig. 9 the larger the angle ϕ, the closer the capacitor voltage comes to the maximum value of the applied voltage; thus there is more contribution and consequently a larger dip, as seen from Fig. 10(A). At the critical value of the phase angle ϕ_c, the initial increase of capacitor voltage with conduction angle and the corresponding contribution to the volt-time area necessary to raise the flux is comparatively small, so that it is just neutralized by the effect of increase in the value of applied voltage. Hence for values of $\phi<\phi_c$ the circuit is stable. Regarding the critical conduction angle α_{cc} corresponding to the firing voltage, Fig. 10(A), shows that for values of $\phi>\phi_c$ this angle increases with ϕ reaching a maximum; it then reduces as the phase angle is further increased. In explanation of this action it may be seen that the angle α_{cc} is dependent on two factors:

1. The negative slope of the characteristics down to the point of minimum dip and the following positive slope. Both these slopes increase with the value of ϕ because of the larger capacitor voltage. Hence, assuming a fixed dip for the sake of argument, it may be seen that the larger these slopes, the smaller the angle α_{cc}.
2. If fixed slopes for the characteristics are assumed it may be seen that the larger the dip corresponding to a larger ϕ, the larger the angle α_{cc}.

If these two factors are considered simultaneously it may be concluded that as the value of ϕ is gradually increased beyond its critical value, the second effect predominates at first; thus the angle α_{cc} increases to a maximum point after which the first effect predominates; consequently α_{cc} reduces for further increase in ϕ.

If it is desired to find a relationship between α_{cc} and ϕ, substitute 0.707×10^{-8} for $E/AB_sN\omega$ in equation 6, while a relationship between the critical extinction angle α_{cc}' and ϕ may be obtained by differentiating equation 6 with respect to α_c and equating the resulting equation to zero.

Conclusions

The set of universal characteristics obtained on the basis of idealized assumptions show good correlation with practical measurement, obtained by experimenting on Deltamax reactors. Thus the behavior of such reactors and future reactors of similar magnetization character in series with capacitance may be predicted from the given characteristics, which are easy to use for design purposes, and very convenient since they may be applied to reactors of any size and at any such reasonably low frequency that the assumptions made are not violated. The analysis may be extended further to practical magnetic-amplifier circuits with capacitive loads, which will be treated in another paper. The analysis given, based on the variation of conduction angle, is a new approach to the problem of instability, giving a better physical picture to the peculiarity in the behavior of the circuit.

Appendix I. Relationship Between Firing Angle and Conduction Angle

The differential equation describing the operation of the circuit of Fig. 3 during saturation is of the form

$$Ri+\frac{1}{C}\int idt=\sqrt{2}\,E\sin\omega t$$

which may be written

$$\frac{di}{dt}+\frac{i}{CR}=\sqrt{2}\frac{E\omega}{R}\cos\omega t$$

Solution of this equation for the current gives

$$i=\frac{\sqrt{2}E}{\left(R^2+\frac{1}{\omega^2C^2}\right)^{1/2}}\sin\left(\omega t+\tan^{-1}\frac{1}{\omega CR}\right)+K\epsilon^{-\frac{1}{\omega CR}\times\omega t}$$

Letting $\phi=\tan^{-1}\frac{1}{\omega CR}$ in this equation gives

$$i=\frac{\sqrt{2}E}{R\sec\phi}\sin(\omega t+\phi)+K\epsilon^{-\tan\phi\times\omega t} \qquad (9)$$

The capacitor voltage at both instants when $\omega t=\alpha_f$ and $\omega t=\alpha_f+\alpha_c$ are equal. The polarity of this voltage is at $\omega t=\alpha_f$ to help the instantaneous applied voltage, while the reverse is true for the instant when $\omega t=\alpha_f+\alpha_c$; see Fig. 6. Thus at $\omega t=\alpha_f$

$$i=i\alpha_f=\frac{\sqrt{2}E}{R}\sin\alpha_f+\frac{V}{R}$$

Substituting this condition in equation 9 gives

$$\frac{\sqrt{2}E}{R}\sin\alpha_f+\frac{V}{R}=\frac{\sqrt{2}E}{R\sec\phi}\sin(\alpha_f+\phi)+K\epsilon^{-\tan\phi\times\alpha_f}$$

from which K may be evaluated and is given as

$$K=\left(\frac{\sqrt{2}E}{R}\sin\alpha_f+\frac{V}{R}-\frac{\sqrt{2}E}{R\sec\phi}\times\sin(\alpha_f+\phi)\right)\epsilon^{+\tan\phi\times\alpha_f}$$

Substituting this value of K back in equation 9 gives

$$i=\frac{\sqrt{2}E}{R\sec\phi}\left\{\sin(\omega t+\phi)+\left[\sec\phi\sin\alpha_f+\frac{V\sec\phi}{\sqrt{2}E}-\sin(\alpha_f+\phi)\right]\epsilon^{-\tan\phi(\omega t-\alpha_f)}\right\}$$

Substituting the second boundary condition $i=0$ at $\omega t=\alpha_f+\alpha_c$, shown in Fig. 6 in this equation, gives

$$0=\sin(\alpha_f+\alpha_c+\phi)+\left(\sec\phi\sin\alpha_f+\frac{V}{\sqrt{2}E}\sec\phi-\sin(\alpha_f+\phi)\right)\epsilon^{-\tan\phi(\alpha_f+\alpha_c-\alpha_f)}$$

from which

$$\epsilon^{+\alpha_c\times\tan\phi}\times\sin(\alpha_f+\alpha_c+\phi)=\sin(\alpha_f+\phi)-\sec\phi\sin\alpha_f-\frac{V}{\sqrt{2}E}\sec\phi$$

to expand

$$\epsilon^{+\alpha_c\times\tan\phi}[\sin\alpha_f\cos(\alpha_c+\phi)+\cos\alpha_f\sin(\alpha_c+\phi)]=\sin\alpha_f\cos\phi+\cos\alpha_f\sin\phi-\sec\phi\sin\alpha_f-\frac{V\sec\phi}{\sqrt{2}E} \qquad (10)$$

As was shown, $V=\sqrt{2}E\sin(\alpha_f+\alpha_c)$; see Fig. 6

therefore $\frac{V}{\sqrt{2}E}=\sin(\alpha_f+\alpha_c)=\sin\alpha_f\cos\alpha_c+\cos\alpha_f\sin\alpha_c$

Substituting this value of $V/\sqrt{2}E$ in equation 10 gives

$$\epsilon^{+\alpha_c\times\tan\phi}[\sin\alpha_f\cos(\alpha_f+\phi)+\cos\alpha_f\sin(\alpha_c+\phi)]=\sin\alpha_f\cos\phi+\cos\alpha_f\sin\phi-\sec\phi\sin\alpha_f-\sec\phi\sin\alpha_f\cos\alpha_c-\sec\phi\cos\alpha_f\sin\alpha_c$$

Dividing both sides of this equation by $\cos\alpha_f$ gives

$$\epsilon^{+\alpha_c\times\tan\phi}[\tan\alpha_f\cos(\alpha_f+\phi)+\sin(\alpha_c+\phi)]=\tan\alpha_f\cos\phi+\sin\phi-\sec\phi\tan\alpha_f-\sec\phi\cos\alpha_c\tan\alpha_f-\sec\phi\sin\alpha_c$$

Solving for $\tan\alpha_f$ gives

$$\text{Tan}\,\alpha_f=\left(\frac{\sin\phi-\sec\phi\sin\alpha_c-\sin(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}{\sec\phi-\cos\phi+\sec\phi\cos\alpha_c+\cos(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}\right) \qquad (11)$$

from which

$$\alpha_f=\tan^{-1}\times\left(\frac{\sin\phi-\sec\phi\sin\alpha_c-\sin(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}{\sec\phi-\cos\phi+\sec\phi\cos\alpha_c+\cos(\alpha_c+\phi)\epsilon^{+\alpha_c\times\tan\phi}}\right)$$

This equation relates the firing angle to the conduction angle for any fixed value of ϕ.

Appendix II. Relationship Between Applied Voltage and Conduction Angle

The differential equation describing operation of the circuit of Fig. 3 in the presaturation region is of the form

$$N\frac{d\Phi}{dt}\times10^{-8}=V+\sqrt{2}E\sin\omega t$$

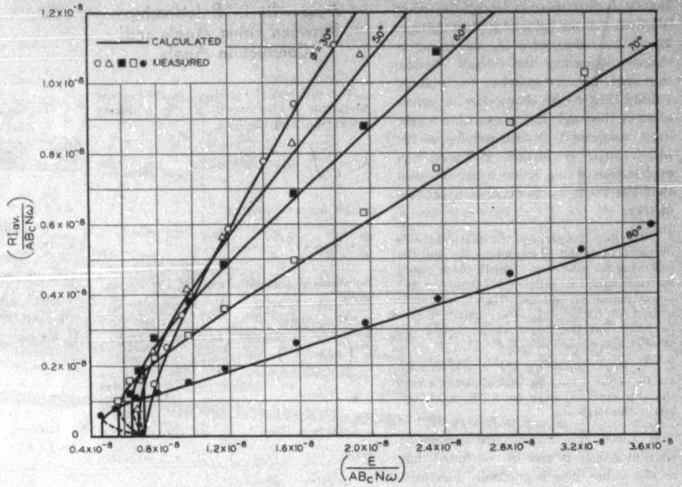
Since $d\Phi=Ad\beta$

therefore $d\beta=\frac{\sqrt{2}E\times10^8}{AN}\left(\frac{V}{\sqrt{2}E}+\sin\omega t\right)$

To integrate

$$\beta=K_1+\frac{\sqrt{2}E\times10^8}{AN}\int_{t_1}^{t}\left(\frac{V}{\sqrt{2}E}+\sin\omega t\right)dt \qquad (12)$$

Fig. 13. Comparison of measured and calculated relationship between applied voltage and average current expressed in nondimensional form. Measurements were made for experimental reactor of Fig. 4 connected in series with fixed capacitor of 1 microfarad and variable resistor adjusted to give appropriate values of phase angle, supplied from variable voltage source at 60 cps. Average load current estimated from areas of current oscillograms; measured $1/AB_cN\omega = 0.0164 \times 10^{-8}$



This equation simply says that the instantaneous value of flux density is equal to an initial flux density, plus a varying flux density proportional to the volt-time area of the applied voltage.

As seen from Fig. 6, the contribution of the flux to initiate a positive pulse of current beginning at $\omega t = \alpha_f$ starts the instant at which the preceding negative pulse of current drops to zero, i.e., at $\omega t = -[\pi - (\alpha_f + \alpha_c)] = \alpha_f + \alpha_c - \pi$. At this particular instant, the core is still saturated in the negative direction, thus $K_t = -B_c$. Substituting these two conditions in equation 12 gives

$$\beta = -B_c + \frac{\sqrt{2}E \times 10^8}{AN\omega}\int_{\alpha_f+\alpha_c-\pi}^{\omega t}\left(\frac{V}{\sqrt{2}E} + \sin \omega t\right) d\omega t = -B_c + \frac{\sqrt{2}E \times 10^8}{AN\omega} \times \left(\frac{V}{\sqrt{2}E}\,\omega t - \cos \omega t\right)_{\alpha_f+\alpha_c-\pi}^{\omega t}$$

At the instant when firing takes place $\beta = +B_c$ and $\omega t = \alpha_f$, thus

$$B_c = -B_c + \frac{\sqrt{2}E \times 10^8}{AN\omega} \times \left(\frac{V}{\sqrt{2}E}\,\omega t - \cos \omega t\right)_{\alpha_f+\alpha_c-\pi}^{\alpha_f}$$

Since $\cos(\alpha_f + \alpha_c - \pi) = -\cos(\alpha_f + \alpha_c)$

therefore $2B_c = \dfrac{\sqrt{2}E \times 10^8}{AN\omega} \times$

$$\left(\frac{V}{\sqrt{2}E}(\pi - \alpha_c) - \cos \alpha_f - \cos(\alpha_f + \alpha_c)\right)$$

from which

$$\frac{E}{AB_cN\omega} = \frac{\sqrt{2}}{10^8} \times \left(\frac{1}{\dfrac{V}{\sqrt{2}E}(\pi - \alpha_c) - \cos \alpha_f - \cos(\alpha_f + \alpha_c)}\right)$$

But $V = \sqrt{2}E \sin(\alpha_f + \alpha_c)$

$$\frac{E}{AB_cN\omega} = \frac{\sqrt{2}}{10^8} \times \left(\frac{1}{(\pi - \alpha_c)\sin(\alpha_f + \alpha_c) - \cos \alpha_f - \cos(\alpha_f + \alpha_c)}\right) \quad (13)$$

The relation between α_f and α_c is expressed by equation 11. When equation 11 is substituted in equation 13 the variable α_f may be eliminated and the voltage may be expressed in terms of a single variable α_c. This substitution may be performed directly; however, to obtain a compact solution, equation 13 may be written

$$\frac{E}{AB_cN\omega} = \frac{\sqrt{2}}{10^8}\left\{\frac{1}{[(\pi - \alpha_c)\sin \alpha_c - \cos \alpha_c - 1]\cos \alpha_f + [(\pi - \alpha_c)\cos \alpha_c + \sin \alpha_c]\sin \alpha_f}\right\}$$

Division of numerator and denominator by $\cos \alpha_f$ gives

$$\frac{E}{AB_cN\omega} = \frac{\sqrt{2}}{10^8}\left\{\frac{\sec \alpha_f}{[(\pi - \alpha_c)\sin \alpha_c - \cos \alpha_c - 1] + [(\pi - \alpha_c)\cos \alpha_c + \sin \alpha_c]\tan \alpha_f}\right\}$$

Substitution of equation 11 in this equation gives

$$\frac{E}{AB_cN\omega} = \frac{\sqrt{2}}{10^8}\left\{\frac{\sec \phi \times \tan^{-1}\left(\dfrac{\sin \phi - \sec \phi \sin \alpha_c - \sin(\alpha_c + \phi)\epsilon^{+\alpha_c \times \tan \phi}}{\sec \phi - \cos \phi + \sec \phi \cos \alpha_c + \cos(\alpha_c + \phi)\epsilon^{+\alpha_c \times \tan \phi}}\right)}{[(\pi - \alpha_c)\sin \alpha_c - \cos \alpha_c - 1] + [(\pi - \alpha_c)\cos \alpha_c + \sin \alpha_c]\left(\dfrac{\sin \phi - \sec \phi \sin \alpha_c - \sin(\alpha_c + \phi)\epsilon^{+\alpha_c \times \tan \phi}}{\sec \phi - \cos \phi + \sec \phi \cos \alpha_c + \cos(\alpha_c + \phi)\epsilon^{+\alpha_c \times \tan \phi}}\right)}\right\}$$

For any fixed value of ϕ this equation relates the applied voltage to the conduction angle where for a given frequency $\dfrac{1}{AB_cN\omega}$ is a constant of the reactor.

Appendix III. Relationship Between Average Value of Load Current and Conduction Angle

The magnitude of the voltage across the capacitor at both instants when $\omega t = \alpha_f$ and $\omega t = \alpha_f + \alpha_c$ are equal in magnitude, but opposite in polarity. This could be seen easily from Fig. 6. Consequently the same is true for the charge across the capacitor. The change in charge from $-Q$ at $\omega t = \alpha_f$ to $+Q$ at $\omega t = \alpha_f + \alpha_c$ is due to the current pulse flowing through the capacitor; this change may be expressed by

$$+Q = -Q + \frac{1}{\omega_c}\int_{\alpha_f}^{\alpha_f+\alpha_c} i\,d\omega t$$

Solving for Q gives

$$Q=\frac{1}{2\omega}\int_{\alpha_f}^{\alpha_f+\alpha_c} i\,d\omega t$$

Thus

$$V=\frac{Q}{C}=\frac{1}{2\omega C}\int_{\alpha_f}^{\alpha_f+\alpha_c} i\,d\omega t=\frac{\pi}{2\omega C}\times \frac{1}{\pi}\int_{\alpha}^{\alpha_f+\alpha_c} i\,d\omega t=\frac{\pi}{2\omega C}I_{\text{avg}}$$

from which

$$I_{\text{avg}}=\frac{2\omega C}{\pi}V=\frac{2\omega CR}{R\pi}V=\frac{2\cot\phi}{\pi R}V \tag{14}$$

But

$$V=\sqrt{2}E\sin(\alpha_f+\alpha_c) \tag{15}$$

Substituting equation 14 in equation 15 gives

$$I_{\text{avg}}=\frac{2\sqrt{2}}{\pi R}\cot\phi\times E\sin(\alpha_f+\alpha_c)$$

This equation may be put into a form more convenient for practical use, as

$$\frac{RI_{\text{avg}}}{AB_cN\omega}=\frac{2\sqrt{2}\cot\phi}{\pi}\,\frac{E}{AB_cN\omega}\sin[\alpha_f+\alpha_c)$$

Substitution of equation 13 in this equation gives

$$\frac{RI_{\text{avg}}}{AB_cN\omega}=\frac{4\times10^{-8}}{\pi}\cot\phi\times \left[\frac{\sin(\alpha_f+\alpha_c)}{(\pi-\alpha_c)\sin(\alpha_f+\alpha_c)-\cos\alpha_f-\cos(\alpha_f+\alpha_c)}\right] \tag{16}$$

The relation between α_f and α_c is expressed by equation 11. By substituting this relation in equation 16, α_f may be eliminated and the average current expressed in terms of a single variable α_c. The substitution may be performed directly; however, to obtain a more compact solution the following manipulation is convenient. Equation 16 may be written

$$\frac{RI_{\text{avg}}}{AB_cN\omega}=\frac{4\times10^{-8}}{\pi}\cot\phi\times \left[\frac{(\sin\alpha_f\cos\alpha_c+\cos\alpha_f\sin\alpha_c)}{(\pi-\alpha_c)(\sin\alpha_f\cos\alpha_c-\cos\alpha_f\sin\alpha_c)-(\cos\alpha_f\cos\alpha_c-\sin\alpha_f\sin\alpha_c)-\cos\alpha_f}\right]$$

Dividing numerator and denominator by $\cos\alpha_f$ gives

$$\frac{RI_{\text{avg}}}{AB_cN\omega}=\frac{4\times10^{-8}}{\pi}\cot\phi\times \left\{\frac{(\sin\alpha_c+\cos\alpha_c\times\tan\alpha_f)}{[(\pi-\alpha_c)\sin\alpha_c-\cos\alpha_c-1]+[(\pi-\alpha_c)\cos\alpha_c+\sin\alpha_c]\tan\alpha_f}\right\}$$

Substitution of equation 11 in this equation gives the equation shown in the following.

For any fixed value of $\phi=\tan^{-1}\dfrac{1}{\omega CR}$ this equation relates the average value of the load current to the applied voltage, where for a given frequency $1/AB_cN\omega$ is a constant of the reactor.

◆

Discussion

George C. Feth (Carnegie Institute of Technology, Pittsburgh, Pa.): The author's core idealization introduces a convenient simplification in the problem, that is hereby reduced to one of solving numerically certain transcendental equations and presenting the results systematically. However, some clearer indication would be desirable concerning the range of the pertinent circuit parameters over which the assumptions, and thus also the results, can be applied.

The idealization used neglects both the width of the hysteresis loop and its slope in the saturated region. In the operation of a circuit using such a rectangular loop reactor and a series load containing a constant resistance, inductance, or capacitance the magnetizing current which flows while the core is unsaturated causes voltage drops in the load. For small values of capacitance or large values of resistance or inductance these drops may be appreciable in comparison with the saturation voltage of the core; thus the critical supply voltage at which saturation of the core first occurs is not independent of the load used.

Moreover, when capacitive loads are used, as the supply voltage is increased above the critical voltage, a kind of resonance or exchange of energy may occur between the capacitor and the nonlinear saturated inductance of the core. The "resonant frequency" of this mode of operation is dependent upon voltage as well as the circuit parameters; several unidirectional peaks of current may occur in a single half-cycle.

Moreover, the operation of the circuit may no longer be periodic on one cycle of supply voltage but may contain subharmonics or may not be periodic at all. These oscillations of current may even swing the core back into the unsaturated region.

These phenomena, which have been recognized for poorer grade, less "square," core materials, also occur with the newer materials. For instance, with an Orthonol core of 0.002-inch tape, inside diameter 1¹/₄ inches, outside diameter 1³/₄ inches, height 1 inch, all of these phenomena were observed on a 200-turn winding at 60 cycles with series capacitance in the range 0.1 to 10 microfarads. With much larger values of capacitance these effects are less noticeable, as would be expected.

Jalal T. Salihi: I wish to thank Mr. Feth for bringing up some points of interest along which further investigations may be made. It is well recognized that the width of the hysteresis loop and its slope imposes limitations on the validity of the idealized analysis presented in this paper. However, for reactors using core materials such as Deltamax and Orthonol there is a wide range of parameters over which the idealized assumptions are closely met. This is because such core materials have a narrow width of hysteresis loop; a high value of presaturation inductance; and a low value of saturation inductance, compared with less nearly perfect core materials. Consequently, for a given phase angle the resistance of the circuit may be increased appreciably without causing noticeable voltage drop in the load associated with the magnetization current. Also, the value of load capacitance may be reduced appreciably before its capacitive reactance reaches a value comparable with the inductance of the core to cause interaction and consequent oscillation. Thus, for reactors using such cores the limitation imposed on the analysis of operation by the maximum value of load resistance and the minimum value of capacitance leaves a

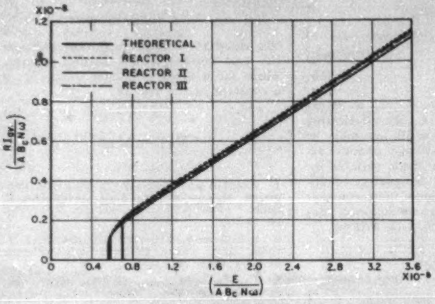

Fig. 14. Comparison of theoretical results with practical measurements made on three reactors of different sizes

145	1.5	85°18′
200	1.1	85°30′
300	0.7	85°30′
500	0.35	86°12′
1,000	0.15	86°48′
2,000	0.075	86°48′
4,000	0.035	87°

wide range of operation satisfying the idealized assumptions. It may also be seen that during this range the core is well utilized as far as power output is concerned, while high values of resistance and low values of capacitance cause a reduction in power output.

A comparison of theoretical results with practical measurements made on three reactors of different sizes is given in Fig. 14, showing good agreement. The size and core material of the reactors used are as in Table I. The effective resistance $R=R_w+R_L$ in series with the reactors are 250, 100, and 100 ohms respectively, while the phase angles were fixed at 70 degrees. The values of $1/AB_cN\omega$ for each reactor was measured by the method described in this paper and are tabulated. The average value of load current was read from a d-c ammeter supplied by a bridge rectifier composed of silicon rectifiers (*1N 338*). The correlation between theory and experiment seen in Fig. 14 is a typical example and may be obtained for a wide range of parameters.

To study the limitation imposed on the value of parameters for good check with theory, the effect of both the width of the hysteresis loop and its slope on the behavior of the circuit are considered. The effect of each may be considered separately as follows.

Limitation Due to Width of Hysteresis Loop

The limitation imposed by the magnetization current on the validity of the idealized analysis may be seen from Fig. 15, where theoretical characteristic for $\phi=70$ degrees is compared with three measured characteristics obtained by measurements on the experimental reactor of Fig. 4. The measured characteristics correspond to three widely different values of resistances of 3,000, 5,000, and 20,000 ohms, and a fixed value of phase angle of 70 degrees. From examination of Fig. 15, it may be concluded that for the given reactor, and assuming a phase angle of 70 degrees, the effect of magnetization current on the behavior of the circuit is almost negligible up to a load resistance of 3,000 ohms. Thus for $\phi=70$ degrees and $R\leq 3{,}000$ ohms the firing and extinction voltages are practically independent of the load. At higher values of load resistance the effect of magnetization current appears, causing a change in the firing characteristic. Thus, as the load resistance is increased, the firing and the extinction voltages increase and the separation between them reduces till they become hardly distinguishable at a load resistance $R=20{,}000$ ohms. The jump in current may be eliminated completely at higher values of resistance.

Knowing the behavior of one reactor at a certain phase angle, we can predict the behavior of other reactors from the following nondimensional consideration. This holds true for the cases corresponding to $R\leqq 3{,}000$ for the experimental reactor, where, as seen from Fig. 15, the effect of the magnetization current is noticeable but not large enough to disturb the nondimensional relationship between $E/AB_cN\omega$ and $RI_{avg}/AB_cN\omega$. Thus, let two reactors have identical operation, i.e., having equal values of conduction angle and phase angle, and let I_m/I_{avg} denote the ratio of magnetization current to the average value of saturation current at the given conduction angle. Making this ratio the same for both reactors gives

$$\frac{I_{m1}}{I\text{avg}_1}=\frac{I_{m2}}{I\text{avg}_2}$$

This may be written as

$$\frac{\dfrac{R_1I_{m1}}{A_1N_1B_{c1}\omega_1}}{\dfrac{R_1I\text{avg}_1}{A_1N_1B_{c1}\omega_1}}=\frac{\dfrac{R_2I_{m2}}{A_2N_2B_{c2}\omega_2}}{\dfrac{R_2I\text{avg}_2}{A_2N_2B_{c2}\omega_2}}$$

Since the conduction angles of both reactors are equal, the denominator of both sides of this equation are equal, thus

$$\frac{R_1I_{m1}}{A_1N_1B_{c1}\omega_1}=\frac{R_2I_{m2}}{A_2N_2B_{c2}\omega_2} \tag{17}$$

But

$$I_m\alpha\frac{H_cl}{N} \tag{18}$$

Thus, from equations 17 and 18

$$\frac{R_2}{R_1}=\frac{A_2N_2^2B_{c2}\omega_2l_1H_{c1}}{A_1N_1^2B_{c1}\omega_1l_2H_{c2}} \tag{19}$$

This equation gives the condition of equal ratios of saturation to magnetization current at equal values of phase angles and equal conduction angles, for two reactors of different sizes. For two reactors using the same core material and the same supply frequency

$$R_2=\frac{A_2N_2^2l_1}{A_1N_1^2l_2}R_1$$

Applying this equation to reactor 3, and the experimental reactor of Fig. 4 having a resistance of 3,000 ohms in the load, gives

$$R_3=\frac{(1.37)(600)^2\times 16}{(0.24)(5{,}000)^2\times 14.4}3{,}000=274\text{ ohms}$$

Thus, it may be concluded that at a phase angle of $\phi=70$ degrees, the effect of magnetization current on the behavior of reactor 3 is almost negligible for values of $R<274$ ohms. At $R=274$ ohms the deviation from the idealized analysis corresponds to the curve $R=3{,}000$ of Fig. 15.

LIMITATION DUE TO SLOPE OF MAGNETIZATION CHARACTERISTIC

If the value of capacitance in the circuit is made sufficiently small, then as the applied voltage is increased the circuit undergoes a chain of irregular modes of operation as described by Mr. Feth. However, measurement on the experimental reactor of Fig. 4 indicates that such a phenomenon takes place only when the load is so highly capacitive that the phase angle exceeds 85 degrees. Thus, for all values of $0<\phi<85$, the idealized analysis controls the operation of the reactor considered. This conclusion was arrived at from an observation of the experimental circuit where the value of load resistance was fixed and the behavior of the circuit was observed as $E/AB_cN\omega$ was increased from zero to 3.6×10^{-8}, at different settings of the capacitor. For values of capacitance sufficiently small the behavior is characterized by the appearance of additional pulses of current in a single half-cycle, which may increase in number as the applied voltage is increased. Up to four of these pulses were noticed. In the range of the applied voltage extending between two of the pulses, oscillation and other phenomena may occur. For a given value of load resistance the number of these pulses is reduced as the value of load capacitance is increased. Consequently, for a given range of applied voltage there is a minimum value of load capacitance at which the appearance of the pulses may be eliminated. For the experimental circuit the minimum value of capacitance corresponding to different values of resistance in the circuit was measured; see Table II. Thus, the maximum value of $\phi=\tan^{-1} 1/\omega CR$ is practically constant, and independent of load.

From these results the following conclusions may be made regarding the operation of the experimental circuit:

1. There is only a narrow range of phase angle $85<\phi<90$ degrees where the idealized analysis in this paper fails, and where subharmonic oscillation and other nonlinear phenomena may occur.
2. The restriction on the minimum value of load capacitance is not imposed by a resonance phenomenon, but rather by the value of load resistance such that ϕ remains constant at about 85 degrees. The nonlinear phenomena described occur at smaller values of capacitance.
3. The statement made by Mr. Feth that the nonlinear phenomena described are due to a kind of resonance or exchange of energy between the capacitor and the nonlinear saturated inductance does not seem to be justifiable. Reactors using Deltamax and Orthonol cores are known for their small values of saturated inductance. For example, in reference 2, the saturation reactance of the experimental reactor of Fig. 4 is estimated at about 10 ohms at 60 cycles per second. This is hardly noticeable when compared with the values of capacitive reactance at which these phenomena occur. Consequently it is more reasonable to associate the phenomena with higher values of inductance, such as the presaturation inductance. Values of capacitance associated with capacitive reactances comparable to the saturation inductance are of the order of several hundreds of microfarads. No investigation was made at such high values of capacitance, where there might be the possibility of nonlinear oscillations. This may impose limitation on the maximum value of capacitance which may be used in the range where the idealized analysis is applicable. However, it may be seen that the range of phase angle at which the capacitance reaches such high values is only a few degrees even at the minimum value of resistance determined by the winding resistance of 145 ohms for the experimental reactor considered.

Low-Impedance Operational Characteristics of Toroidal Cores Used in Magnetic Amplifiers

C. L. BOYAJIAN
ASSOCIATE MEMBER AIEE

Synopsis: The need for knowing the low-impedance operating characteristics of a toroidal core or cores to be used in a magnetic amplifier operating under low-impedance control conditions is shown in this paper. A method is then presented for determining these low-impedance characteristics without first winding turns on the core. This method is presented for the edification of persons who are working on the development of new core-testing techniques.

Encouraging results of a preliminary investigation of this low-impedance testing method are shown.

MANY magnetic amplifiers approach low-impedance control operation. For this reason, it is desirable to have a method for testing cores used in these amplifiers which will simulate low-impedance control operation.

The testing method to be used must be so designed to predict satisfactorily the characteristics of the core for such operation without the need for first winding a large number of turns on the core. Most testers presently being used, which fulfill the latter requirement by using multiple-turn connectors or similar test jigs, operate on a high-impedance control principle. The most commonly used methods are the constant-current reset test method,[1,2] and the sine-current test method.

These methods produce good results for high-impedance-control magnetic-amplifier applications, but the results are not as good for use with low-impedance-control magnetic amplifiers. A more accurate determination of the operational characteristics of toroidal cores used in low-impedance control operation is desirable for applications requiring more accurate matching of cores than now possible.

Data comparing the core characteristics measured on a constant-current reset core tester with those measured on an actual low-impedance-control magnetic amplifier, confirmed the need for a method to determine the low-impedance operating characteristics of a core.

Determination of Mode of Operation of a Magnetic Amplifier

The need for a low-impedance-type test method was also made apparent by the results of an investigation to determine the type of impedance control operation of a magnetic amplifier.

The power gain and/or drift requirements of many low-power magnetic-amplifier applications require that the amplifier time constant be approximately 1/100 seconds or longer. This applies to applications operating at supply frequencies in the vicinity of 400 cycles per second (cps) or less.

The mode of operation of a full-wave

Paper 56-220, recommended by the AIEE Magnetic Amplifiers Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 19, 1955; made available for printing December 15, 1955.

C. L. BOYAJIAN is with General Electric Company, Schenectady, N. Y.

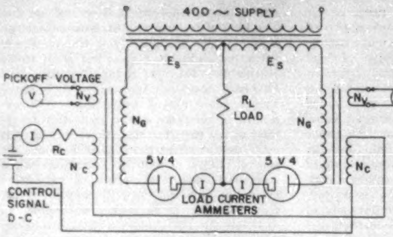

Fig. 1. Full-wave center-tapped circuit used for measuring amplifier control characteristics. Electronic tubes used for ideal rectifiers

center-tapped magnetic amplifier designed with a time constant of 1/100 seconds was investigated to determine the type of impedance control operation under which this amplifier can be classified.

Method of Obtaining Data

A full-wave center-tapped circuit as shown in Fig. 1 was used for the investigation. Two types of materials were investigated: Deltamax, (50-per-cent (%) nickel-iron grain-oriented 2-mil tape) and Supermalloy (79% nickel, 5% molybdenum, 16% iron, 2-mil tape). The size of the Supermalloy and Deltamax cores used is 1.0 inch inside diameter (ID) by 1.375 inches outside diameter (OD) by 0.25 inch. Two matched cores of each type, with average characteristics, were selected and wound for the full-wave center-tapped circuit. Electronic diodes were used instead of metallic rectifiers to eliminate the leakage current and capacitance effects. Only 400-cps operation was investigated.

To determine the effect of the control circuit impedance on the operation of the amplifier, the following conditions of control impedance were observed: (a) low impedance, an N^2/R ratio$=1{,}000$, with as low a control resistance as practically possible to allow the free flow of the induced harmonic currents (the N^2/R ratio is the ratio of the control turns squared to the total control circuit resistance. This ratio is used as a figure to represent the type of impedance control operation of the magnetic amplifier); (b) intermediate impedance, resulting in an amplifier time constant of 1/100 seconds—for the Deltamax cores, $N^2/R=160$, for the Supermalloy cores, $N^2/R=40$; (c) high impedance, with an N^2/Z ratio approaching zero obtained by using a 10-henry choke in the control circuit to oppose the flow of induced harmonic currents so as to maintain a steady d-c control current (the Z is the total impedance of the control circuit); (d) in addition, a control impedance condition with $N^2/R=10$ was investigated. This condition falls between the high- and intermediate-impedance operation but approaches the high-impedance control condition.

Results of Gain Curve Comparisons

Amplifier gain curves were taken for each of the afore-mentioned conditions. The results are shown in Figs. 2 and 3. The results of Fig. 2 show that with Deltamax, there is an appreciable shift to the right as the control impedance is decreased. The gain also decreases in this direction. The important observation, however, is the closeness of the intermediate- and low-impedance gain curves. This seems to indicate that the intermediate-impedance operation approaches the low-impedance operation.

Fig. 3 shows an entirely different characteristic for Supermalloy. As the control impedance is decreased, the gain curve in the linear region shifts to the right and then returns to the left. The intermediate impedance results in the gain curve furthest to the right. From this, one might conclude that the intermediate-impedance condition lies between the high and low cases. No definite conclusion can be made, however.

The magnitude of the supply voltage used to take these gain curves was slightly less than the value that would be equivalent to the voltage induced by a complete flux swing of the core from minus saturation to plus saturation.

The plots of Figs. 2 and 3 show a high cutoff load current. This load current could not be reduced any further because of the high magnetizing current which was necessary as a result of the relatively small number of turns on the gate winding.

Comparison of Wave Forms

The investigation was continued by observing the actual control current and reset voltage wave forms for the conditions of control circuit impedance mentioned previously by use of the same cores. The additional condition of control circuit impedance between the intermediate and high conditions with an N^2/R ratio of 10 was again observed for Supermalloy and Deltamax cores. This was done to show the transition between the intermediate- and high-impedance case since there was a considerable difference. These wave forms are shown in Figs. 4–7. Three firing angles are shown.

The reset voltage is the negative half-cycle in Figs. 5 and 7. The superimposed sine wave in Fig. 5 is for reference only. The sweep as shown is from left to right.

A highly grain oriented nickel-iron core material such as Deltamax exhibits square *B-H* loop properties when a sinusoidal voltage is applied to the core as in low-impedance operation. The reset current for Deltamax, under these low-impedance operating conditions, approaches a square shape as shown in Fig. 4(A). The theoretical explanation of this characteristic wave form is presented in reference 3. Supermalloy, which has a rounded *B-H* loop under low-impedance conditions, would cause a low-impedance reset current wave form that is rounded as shown in Fig. 6(A).

The reset voltage wave form is sinusoidal for the low-impedance operation of both materials as is seen in Figs. 5(A) and 7(A).

As the control circuit impedance is increased, the control current wave shape approaches a constant direct current as shown in Figs. 4(D) and 6(D). The reset voltage is no longer a sine wave but takes on a shape determined by the high-impedance control *B-H* characteristics of the core as seen in Figs. 5(D) and 7(D).

From a comparison of the wave shapes photographed under the intermediate-impedance conditions [Figs. 4(B), 5(B), 6(B), and 7(B)] with those taken under the low-[Figs. 4(A), 5(A), 6(A), 7(A)] and high-[4(D), 5(D), 6(D), 7(D)] impedance conditions, one can conclude that the intermediate case approaches the low-impedance case.

Conclusion

The comparisons of the gain curves and the current and voltage wave forms have shown that this low-power magnetic amplifier with a time constant of 1/100 seconds operates under a condition approaching low-impedance control operation. From these results, it may be concluded that many full-wave magnetic amplifiers operating at supply frequencies of 400 cps or less and designed to have a time constant of 1/100 seconds or less operate under conditions approaching low-impedance-control operation.

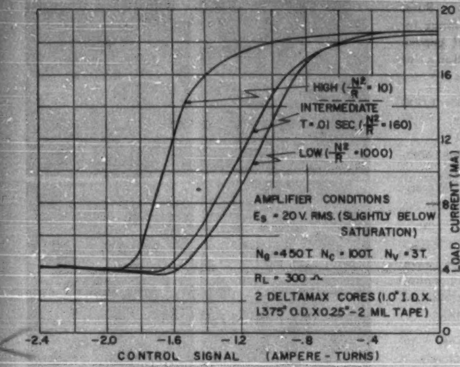

Fig. 2. Amplifier control characteristic curves showing the effects of varying the control circuit impedance on the current gain curves of Deltamax cores in a full-wave center-tapped circuit using electronic diodes

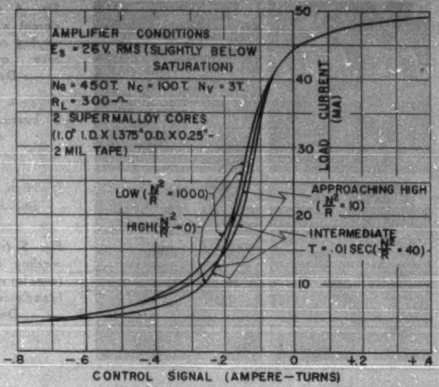

Fig. 3. Amplifier control characteristic curves showing the effects of varying the control circuit impedance on the gain curves of Supermalloy cores in a full-wave center-tap circuit using electronic diodes

In light of this information, the need for a method to determine the low-impedance operational characteristics of a toroidal core is realized.

Low-Impedance Core-Test Method

The work presented in this paper was done in conjunction with an investigation to determine the best methods for testing toroidal cores used in magnetic amplifiers. One of the commonly used core-testing methods, the constant-current reset tester,[1,2] was thoroughly investigated to determine the correlation existing between toroidal-core operating characteristics as measured on the core tester and in an actual full-wave center-tapped magnetic amplifier circuit. A comparison of core gain measurements of Deltamax cores (1-inch ID by 1.375-inch OD by 0.25-inch 2-mil tape) taken with the constant-current reset core tester with those taken with the magnetic amplifier under low-impedance control operation showed poor correlation; see Fig. 8. The method used to take these data will be explained later. Good correlation was not expected under these conditions, however, since the constant-current reset core tester operated under high-impedance control conditions. A comparison of the same core-tester gain data with the gain measurements taken with the magnetic amplifier under high-impedance control operation is shown in Fig. 9. This plot shows the correlation that is presently achieved using this constant-current reset core tester.

In addition, there is no guarantee that cores matched under high-impedance control conditions will be matched when operating under low-impedance control conditions. For many applications, this change in the match is tolerable. However, many applications require an accurate match or measurement of the core characteristics for low-impedance operation.

PROBLEM

The low-impedance core tester must simulate the low-impedance control operation of the amplifier and satisfactorily predict the characteristic of the core for such operation without first winding a large number of turns on the core. To achieve low-impedance operation, a sinusoidal voltage must be applied to the core. A sinusoidal voltage is possible only if the total impedance of the supply circuit, as seen from the turns of the test jig, is very low.

A toroidal core tester, if it is to be of practical value when it tests a large number of cores, must use a multiple-turn connector or test jig of some type to make the required turns around the core for the excitation and pickoff signals. The test jig would eliminate the necessity of winding turns on the core. The physical size of such a test jig greatly limits the number of allowable turns for small-size cores.

A major problem is to maintain the resistance of the test circuit low enough with the few test turns of the connector to achieve a sine-voltage excitation. Most connectors develop increasing contact resistance with use if not continuously cared for. For example, the impedance of the circuit presented in this paper must be of a value to result in a ratio of signal turns squared to total resistance (N^2/R) approximately equal to 1,000.

To simulate the magnetic-amplifier operation, the voltage wave form applied to the core must be as close as possible to that which occurs in the actual amplifier.

In addition to fulfilling these operating requirements, the problem of instrumentation is important. The accuracy of the core test data depends on the accuracy of the instrumentation regardless of how well the circuit simulates low-impedance operation.

The low-impedance test method and circuit described in this paper fulfill all of these requirements in the laboratory.

TESTER OPERATION

The low-impedance core-tester circuit diagram is shown in Fig. 10(A). This tester applies a voltage across the test core with a wave form as shown in Fig. 11. The voltage wave form is sinusoidal until the firing angle at which time the applied voltage drops to a negligible value. The firing angle of the applied voltage is controlled by controlling the firing angle of the thyratron tube V_1.

The basic principle of operation of the circuit is as follows: A sinusoidal voltage of a specific value is applied across a specified number of primary turns of saturating transformer T_2. The voltage

is transformed and applied across the turns of the test core, but retains its sinusoidal wave shape. When the thyratron V_1 fires on the first half-cycle or reset, the applied voltage drops to the voltage drop across the thyratron or approximately zero since the ratio of supply voltage to tube drop is made high in the circuit. During the second half-cycle or set, the transformer T_2 will saturate itself at the same point in the half-cycle. Both firing angles occur at the same respective point because the positive volt-time area across a transformer must equal the negative volt-time area. By controlling the volt-time area of one half-cycle, the volt-time area of the second half-cycle is automatically controlled. The resulting applied wave form across the core is approximately symmetrical and the same as would occur across the core in a low-impedance control magnetic amplifier as shown in Figs. 12(A) and (B). These voltage wave forms were measured directly across the core winding of the amplifier and the turns of the test connector. The reset voltage is the negative half-cycle.

The test core does not have to be driven into saturation to operate on its minor loop as it does in a magnetic amplifier. An inherent unbalance in the circuit causes the core always to seek saturation in one direction as is shown in Fig. 14(C). This will be explained later in the detailed description of the circuit operation.

Only the square-loop material Deltamax was investigated. Core materials with *B-H* loop characteristics that differ from the square-loop properties of Deltamax may have to be driven into saturation.

The actual control characteristic of the core, which is a measure of the minor loop characteristics of the core, can be measured with the circuit. The amount of reset of the core from saturation is controlled by the firing angle of the thyratron. If the thyratron fires immediately at the beginning of the cycle, the core will not reset and will remain in saturation simulating the full "on" position of the magnetic amplifier. If the thyratron does not fire at all, the core flux will reset for the entire half-cycle corresponding to the cutoff position of the magnetic amplifier. The maximum amount of reset is determined by the specified voltage transformed by T_2. These are the extremities of the control characteristic.

Correlation Between Tester and Amplifier Data

To determine the ability of the low-impedance core tester to measure the operating characteristics of the toroidal core under low-impedance control conditions, data were taken on the core tester and compared with data taken on the full-wave center-tapped circuit with a low-impedance control. The reactor was made up of two Deltamax cores (1.0-inch ID by 1.375-inch OD by 0.25-inch 2-mil tape).

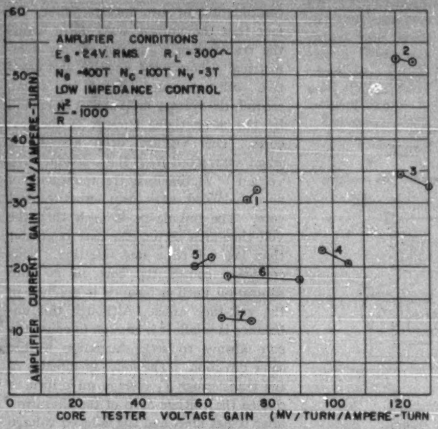

Fig. 8. Comparison of amplifier current gain versus constant-current reset core tester voltage gain for seven matched pairs of Deltamax cores

Grain-oriented 50% nickel-iron 2-mil tape. 1.0 inch ID by 1.375 inch OD by 0.25 inch

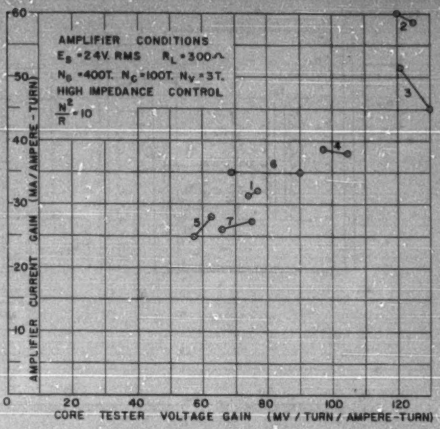

Fig. 9. Comparison of amplifier current gain versus constant-current reset core tester voltage gain for seven matched pairs of Deltamax cores

Seven matched pairs of the Deltamax cores were selected for the tests, with *B-H* loop widths that varied considerably. This was done to produce as wide a spread of characteristics as possible so as to present a more realistic picture of the resulting correlation.

The control characteristic voltage gains of the cores were first measured on the low-impedance core tester as will be explained later. The amplifier current gains were then measured by use of the full-wave center-tapped circuit after each pair of cores was wound into a reactor. Care was taken to measure the gains while operating the core under the same conditions in the tester and the amplifier. Care was also taken to measure the gain over the same region of the control characteristic in both cases. This would eliminate any discrepancies in the data due to nonlinearities in the control characteristic. This same procedure was used to take the data of Figs. 8 and 9.

The amplifier current gain was plotted versus the tester voltage gain and the resulting correlation is shown in Fig. 13. Perfect correlation would result if all the points fell on a straight line passing through zero. Only a representative figure could be used as a measure of the voltage gain of the tester because of the method used to measure the reset current which will be explained later.

The ability of the low-impedance core tester to measure the operating characteristics of a core can be appreciated more by a comparison of the results of Fig. 13 with those of Fig. 8.

Comparison of Tester Operation With Amplifier

The ability of the low-impedance core-test circuit to simulate the actual magnetic amplifier operation under low-impedance control conditions can be shown more clearly by comparing oscillograms of voltage and current wave shapes.

The oscillograms presented are of magnetizing current wave forms, pickoff voltage wave forms, and minor *B-H* loops, and compare the core tester operation with that of the full-wave center-tapped circuit under identical operating conditions.

The magnetizing current wave forms showing the core reset current, which is the portion above the zero axis, are presented in Figs. 14(A) and (B); they show the same core in the core tester and in the amplifier, respectively. A minor *B-H* loop characteristic of a different core in the core tester and in the amplifier, with the same firing angle as in Figs. 14(A) and (B), is shown in Figs. 14(C) and (D).

A comparison of Figs. 14(A) and (B) and 14(C) and (D) shows conclusively that the low-impedance tester closely simulates the actual operation of the magnetic amplifier under low-impedance control conditions.

The reset current portion of the wave forms shown in Figs. 14(A) and (B) differs slightly after the firing angle because of a coupling between the core windings of the magnetic amplifier in the circuit used. In the full-wave center-tapped circuit, when one core comes out of saturation a voltage is induced in the winding of the other core, which is being reset. This causes the reset current to slope towards zero,[3] and occurs in the region after the reset current drops suddenly to the smaller value. The current in Fig. 14(B) slopes towards zero whereas the current in Fig. 14(A) remains horizontal due to the absence of this effect. The magnitude of this effect is small in square-loop materials due to the low slope of the *B-H* loop in saturation.

The magnetizing current wave forms also differ in the region where the core comes out of saturation. In the magnetic amplifier the core is driven far out into saturation whereas in the core tester it is not. This effect is eliminated by use of a mechanical chopper to chop off a small portion of the beginning of the reset half-cycle of current as shown in Fig. 15(B). This elimination is necessary as the slope of that portion where the current goes from the set half-cycle to the reset half-cycle changes with the firing angle because the core is not driven far into saturation as in the actual magnetic amplifier. To eliminate this variable, the chopper is used.

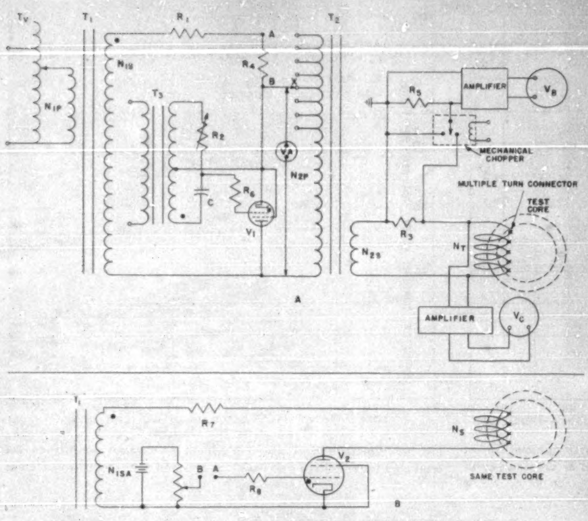

Fig. 10

A—Low-impedance core-tester circuit B—Circuit to drive core into saturation

The chopper is also used to take out the setting half-cycle of the magnetizing current so that only the reset half-cycle of current is metered. Fig. 15(A) shows the current wave form after it has been chopped to be metered. The chopper can perform both of the afore-mentioned functions because it can be made to be effective for only about 150 degrees of the half-cycle.

DETAILED DESCRIPTION OF CIRCUIT OPERATION

The diagram of the circuit to be described in the following is given in Fig. 10.

To test a given core, the core is placed in the loop of the multiple-turn connector and the connection made, closing the path of the test turns N_T about the core. With the thyratron V_1 turned off, the proper tap X of primary winding N_{2p} of T_2 is chosen and variac T_v varied until voltmeter V_A reads a specific prescribed voltage for the size and type of core to be tested. This primary tap and value of specified voltage are chosen so that the voltage applied across the test-core windings N_T will be the same percentage of the core saturation voltage as will be applied to the core in the actual amplifier circuit. This will apply a full sine wave of voltage to the core and simulate the "off" condition of the core.

The firing angle of the thyratron V_1 is varied by varying R_2, and thus the reset of saturable transformer T_2 is controlled. Since the volt-time area of the positive and negative half-cycles of the transformer must be equal, a symmetrical wave shape of voltage, as shown in Fig. 11(A), is applied to the test core. By varying the firing angle of V_1, the firing angle (a) of saturable transformer T_2 is varied. This wave shape is very similar to the one applied across the winding of the core in the actual magnetic amplifier.

As mentioned previously, the test core always seeks saturation in one direction due to an inherent unbalance in the circuit. The unbalance is caused by the combination of two factors: first, the fact that the voltage wave form across the transformer T_2 is not exactly symmetrical although the positive and negative volt-time areas must be equal; second, the voltage drop across R_3 caused by the magnetizing current of the test cores. This voltage drop across R_3, when subtracted from the secondary N_{2s} voltage of T_2, results in the application of an unbalanced wave form across the test core. The unbalance is such that the volt-time area setting the core is greater than the volt-time area resetting. This condition causes the core to go into saturation until a balance is reached in the volt-time areas. Although this unbalance is small, it is enough to cause the core always to seek saturation in the same direction. The small asymmetry of the transformer T_2 voltage wave form is due to the voltage drop of the thyratron after it has fired and the induced voltage by the transformer as it comes out of saturation. Both of these voltages are of the same polarity as can be seen in Fig. 12(A). These voltages are small and do not affect the firing angles of the applied wave form appreciably but they are enough to cause this desirable small unbalance.

To obtain characteristic data on the core being tested, the magnetizing current of the core and the core-induced voltage are measured. The reset portion of the core magnetizing current is measured by metering the drop across R_3. The reset half-cycle of current only, is measured by a mechanical chopper. The reset half-cycle drop across R_3 is then amplified and measured by V_B. The meter can be calibrated to read the equivalent magnetizing current.

The induced voltage is measured directly across the turns on the test core or across a separate pickoff source of three turns on the connector to eliminate any slight inaccuracy due to the very small voltage drop caused by the resistance of turns N_T. The core voltage is meas-

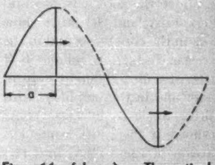

Fig. 11 (above). Theoretical tester voltage wave form

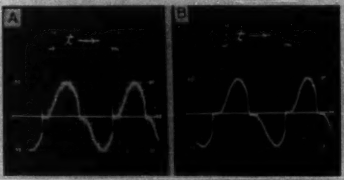

A—Tester B—Amplifier

Fig. 12 (right). Comparison of the voltage wave form applied across the core between the actual amplifier and the low-impedance tester

Control impedance ratio $N^2/R = 800$ for both ured by a meter that amplifies voltage and measures its average value.

From these current and voltage measurements, a complete gain curve for the core may be plotted which will predict the core's characteristics in the actual magnetic-amplifier circuit.

The resistance of R_3 may be varied to simulate any practical level of control impedance desired although the circuit is primarily designed for low-impedance testing.

Step-up transfomer T_1 is used to raise the supply voltage level so as to minimize the effect of the voltage drop across thyratron V_1 when it fires. Resistor R_1 is made only large enough to limit the forward current through V_1 when it is conducting.

The ratio of the test-core turns squared N_T^2 to the total resistance around the paths from N_2, to N_T must be kept extremely low to insure that the voltage applied to the core is sinusoidal. This also applies to the primary circuit of T_1. Care must be taken to keep the contact resistance low in the connector.

If it becomes necessary or desirable to drive the test core into saturation, circuit *10B* may be used.

The polarity of N_{1-4} of T_1 is such that when the saturable transformer T_2 goes into saturation, the drop across R_4, which is connected to points *A* and *B* of circuit *B*, will fire thyratron V_2. The resulting ampere-turns through the few turns of N_3 about the test core will drive the test core into saturation.

It should be noted that the response time of the thyratron is important. For example, to test cores at 400 cps, the thyratron must operate satisfactorily at that frequency.

Conclusion

The results presented in this paper show that this method of testing toroidal cores closely simulates the low-impedance control operation of the actual magnetic amplifier. The good correlation resulting between the gain characteristics measured on the test method and the actual amplifier operating under low-impedance conditions shows that the test method can determine the low-impedance operational characteristics of a core without the necessity for winding a large number of turns around the toroidal core.

A New 4-Channel Open-Wire Carrier System Employing Transistors

R. S. CARUTHERS

W. S. CHASKIN
ASSOCIATE MEMBER AIEE

H. K. KRENGEL
NONMEMBER AIEE

AMONG independent telephone companies, Bell System operating companies, and railroad communications systems, carrier is used to exploit fully the vast mileage of open-wire telephone plant. Consistent with circuit needs, wire lines were first used to transmit voice-frequency circuits and, later, with added transpositions, to transmit carrier circuits employing frequencies to about 35 kc. Even now, after more than 30 years of such growth, however, the great majority of open-wire message traffic for short- and medium-haul distances is transmitted at carrier frequencies below 35 kc. The number of circuit miles in these carrier frequencies is now in the millions. Continued major growth is expected in open-wire plant, not by adding more wire lines but by moving to higher frequencies.

Past system design practices have generally advocated sufficient transpositions of wire lines to make crosstalk tolerable at the top frequencies of the carrier systems involved. In more recent years, however, the availability of inexpensive compandors has permitted wire lines to be used at frequencies much beyond those previously considered satisfactory from a crosstalk point of view. In the case of 35-kc transposed lines, compandors make the lines suitable for frequencies up to about 80 kc, and thus allow the transmission of four additional carrier channels. Full use of these additional channels will nearly double present open-wire circuit mileage.

This paper describes a 4-channel open-wire carrier system, the Lenkurt type *45CB*, for use in the 40- to 76-kc spectrum above present carrier systems using frequencies up to 35 kc. Channel terminal equipment, including compandors, makes use of miniature equipment already used in other Lenkurt open-wire, radio, and cable carrier systems (the *45A*, *45BX*, and *45BN* respectively). In the common amplifying, carrier generating, and regulating circuits, transistor circuitry has been employed extensively for the first time in a toll carrier system. The transistor circuits include high-gain high-frequency amplifiers with considerable feedback and carrier-generating circuits with highly stable quartz crystals. Design of these transistor circuits has been a highly satisfactory experience, and performance results are excellent. A detailed discussion of the design of transistor circuits for the system is also given.

Electrical Features

As in all types of Lenkurt *45*-class carrier, the first stage of modulation translates the speech frequencies of each message channel into a carrier band in the frequency region from 8 to 24 kc. In the *45CB* system, as indicated in Fig. 1, four channels are derived by modulating carriers of 12 and 20 kc. Channels 1 and 2 are derived from the lower and upper side bands of the 12-kc carrier, and channels 3 and 4 are derived from the lower and upper side bands respectively of the 20-kc carrier. This system of modulation is generally referred to as twin-channel single-side-band operation. The 4-channel band from 8 to 24 kc is further translated to line frequencies in either a 40- to 56-kc band or a 60- to 76-kc band. Where a terminal is transmitting the low-group band, it is receiving the high-group band. This arrangement is termed a low-group transmitting terminal. An alternate high-group transmitting terminal transmits a high group and receives a low group.

In a system without repeaters, a high-group transmitting terminal is required at one end and a low-group transmitting terminal at the other. In repeatered operation, either type may be required at either terminal depending upon the particular system layout. Each repeater transposes low and high groups so that transmission over two or more sections is alternately in high- and low-frequency bands. Such repeaters are commonly called "frequency-frogging repeaters."

In traversing a frequency-frogging repeater, the frequency order of the channels in a group is reversed. This requires that the frequency order of the high and low groups be opposite, so that at end terminals the received group can be properly demodulated. To accomplish the reversal, the low group is formed from the lower side band of a 64-kc carrier and the high group is formed from the upper side band of a 52-kc carrier.

In Fig. 2, a block diagram of the terminal is shown with message and signal levels indicated. To the left are shown the standard compandor and channel equipment used in all *45*-class Lenkurt equipment for open-wire, cable, and radio systems. The wire frequency terminations are arranged for 2- or 4-wire voice-frequency operation at all of the standard telephone transmission levels, which allows either single- or multilink operation in the toll-switching telephone plant.

The equipment common to the four channels is shown to the right and consists of:

1. A transmitting unit which provides amplification and translation between the channel frequencies at 8 to 24 kc and the line frequencies at 40 to 56 kc, or 60 to 76 kc.
2. A receiving unit which provides amplification, regulation, and conversion between line frequencies and the receiving 8- to 24-kc channel band.
3. A combining directional filter unit for transmitting and receiving groups.
4. A carrier supply unit for deriving the group and channel frequencies from two crystal oscillators at 32 and 52 kc.

REGULATION PERFORMANCE

In providing gain and regulation, a common practice is to engineer performance for three sets of line conditions: dry weather, wet weather, and sleet. The amount of sleet designed for is near the maximum the wires can carry without breakage. This is normally considered to be about 1/4 inch of radial-diameter ice and results in about 50 decibels (db) of attenuation for a 70-mile section at the top frequency of the *45CB* system.

In Fig. 3, attenuation characteristics of typical line sections are shown for various weather conditions. Included are curves for 50 miles of lines with 1/4 inch of ice, 100 miles of wet-weather line, and 100 miles of dry-weather line. Also shown are attenuation characteristics for tandem sections with an intervening frequency-frogging repeater. The benefits of frequency frogging in all weather

Paper 56-245, recommended by the AIEE Wire Communications Systems Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 21, 1955; made available for printing December 6, 1955.

R. S. CARUTHERS, W. S. CHASKIN, and H. K. KRENGEL are with the Lenkurt Electric Company, Inc., San Carlos, Calif.

conditions in eliminating slope characteristics are apparent. Bulge across a single channel is so slight that it can be ignored. Because of the small residual slope and bulge, the flat types of regulators provided by repeater and terminal equipment are adequate. Channel regulation supplementing the group regulation corrects the small remainder of level inequality among individual channels.

The adequacy of regulation provided by group- and channel-regulating techniques can be seen from the curves in Fig. 4. These curves show that changes in message output level are so slight through extremes of line loss that satisfactory performance can be expected under most conditions of plant layout. Fig. 5 shows the channel frequency characteristic.

NOISE PERFORMANCE

Design of the system for adequate noise performance entails proper distribution of noise contributions between terminal and line effects during both normal and storm operating periods. During normal periods, most of the noise disturbances to channels result either from various modulation products of signal tones, or from crosstalk disturbances caused by intermodulation products in common amplifiers and modulators. In general, noise performance during normal periods is better than required to allow for the major increases in noise disturbances during adverse weather conditions.

During abnormal weather with severe localized thunderstorms, either signal or message channels, or both, may be seriously affected by atmospheric noise. In Fig. 6, noise measurements are shown observed during field tests. These data are undoubtedly pessimistic, as it was necessary to increase the line attenuation during these heavy, localized storm periods to simulate continuous wet weather over the entire line. It appears doubtful that localized lightning storms will be coincident with steady rain over the whole line section. In field tests, very little increase in attenuation has been observed during the severe local thunderstorm period.

During icing conditions, lines are invariably quite free from high atmospheric noise. Only the terminal and repeater equipment contribute to noise during such periods. However, except for excessive attenuations with heavy icing, where the regulation systems run beyond their ranges, the signaling and speech transmission is nearly as satisfactory as in normal weather periods.

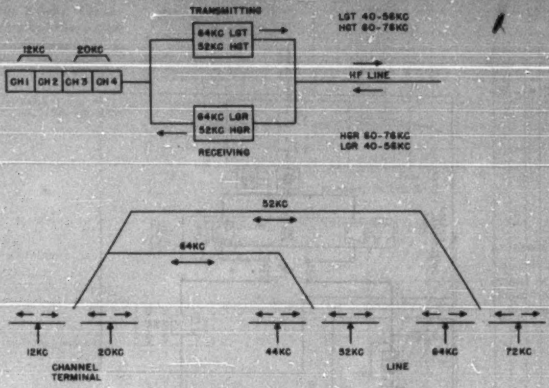

Fig. 1. Modulating plan and frequency allocation

CROSSTALK PERFORMANCE

Since the *45CB* system uses frequencies beyond those originally considered satisfactory, in regard to crosstalk for a 35-kc transposed pair, a major dependence is placed on improvements derived from compandor action. Frequently, both far-end and near-end crosstalk in such wire lines are little more than 30 db below the disturbing source at an equal-level point. During dry-line conditions with low noise, compandor benefit of as little as 23 db (28-db expandor advantage minus 5-db compressor disadvantage) would not be adequate. The Lenkurt compandor, however, gives considerably more advantage than 23 db under these circumstances.

In Fig. 7, the suppression characteristic of the expandor is shown for varying magnitudes of noise and speech crosstalk. For example, a 0-volume-unit (vu) talker (about 1 in 500 talkers) would be effectively raised to +2.5 db referred to 1 milliwatt (dbm) speech power because of compressor action at the zero message level point. The line crosstalk coupling loss of 30 db would present a disturbing crosstalk power to the expandor of about −27.5 dbm. Approximately a 33-db loss in the expandor would reduce crosstalk to about −60 dbm of speech power at the expandor output at the zero level point, or to approximately 60 db below the original disturbing speech.

Table I shows crosstalk expectancy in relation to talker volume. Equal-level crosstalk of 30 db is assumed on the lines and, arbitrarily, a talker is assumed to be talking one-fourth of the time from one end of the circuit (25-per-cent activity factor).

Equipment Features

The terminal equipment is mounted in a small shelf about 16 inches in height. This shelf is completely wired, with fusing and alarms integrated for simple installation on 19-inch relay racks of either duct or channel type. Standard arrangments for back-to-back mounting are employed, with projections no more than 5 inches to the front or in depth from the face of the relay rack. A bottom row of plug-in units, shown in Fig. 8, contains the four compandor units. Next above are the four channel units. Both channel and compandor units are standard for the 45 line of equipment, except that the channel band filters of the *45CB* system are designed for twin-channel operation and take advantage of compandor action to simplify the design. The common equipment units on the top shelf are, from left to right: the fuse alarm unit, the directional filter unit, the receiver regulator unit, the carrier supply unit, and the transmitting amplifier unit. Only 21 vacuum tubes are used in the entire equipment. One of these is in the common equipment, where as yet techniques for wide-range regulation have not permitted substitution of a transistor for the vacuum tube. As in other *45*-type equipment, only long-life miniature triodes and pentodes are used. These tubes have 20-volt heaters permitting operation from 24- or 48-volt office batteries as well as from alternating current. The need for a 130-volt battery for the vacuum tubes makes it economical to design the common-equipment transistor circuitry on a standard 130-volt basis to avoid optional strap-

ping for tube filament battery conditions encountered in various telephone offices.

The total power drain is as follows: For the 48-volt filter battery, 1.01 amperes, and for the 130-volt plate battery, 0.244 ampere.

In Fig. 9, the equipment is shown with plug-in units removed. Twenty-pin gold-plated jacks are shown, with free-floating pins to accommodate similarly gold-plated plugs on the plug-in units. The fuse alarm unit is shown at the upper left, accessible by a hinged-cable arrangement. As in all *45*-type equipment, the locking and camming action of the latch on the individual plug-in units allows simple removal and insertion.

Alarms indicate the fuse or system failure with lights and keys standard in modern toll-office practice. In addition, an auxiliary alarm arrangement used with dialing systems can be associated with the terminal shelf to provide automatic disconnect and automatic busying of signaling circuits in case of system failure. Also, the auxiliary alarm equipment enables operation to remote unattended terminals where a test can be made from the attended terminal as to clearance of line trouble; this is followed by reset of distant alarm relays.

All the common-equipment plug-in units are quite similar in internal construction. Typical is the transmitting unit shown in Fig. 10. Transistors are mounted internally on boards in the same manner as other pigtail components, with the exception that a transistor socket is used. It is expected that transistor sockets will not be required within a short period of time; in fact, they may not be needed now. However, pending more extensive data, transistors are being supplied with a socket to allow their replacement should troubles develop over the next few years. Another benefit of the socket is that, if superior transistors do become available, they may be inserted in the equipment without soldering.

An unusual feature of the carrier supply unit is the employment of a crystal oven with dual crystals at 32 and 52 kc mounted within the same oven. Oven-temperature control to ±1 degree assures high stability of the frequencies for the channel carriers as well as the group carriers.

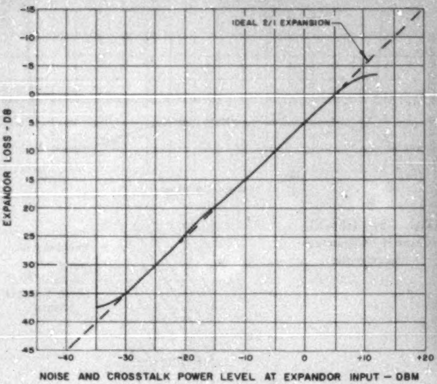

Fig. 7. Expandor noise suppression characteristic

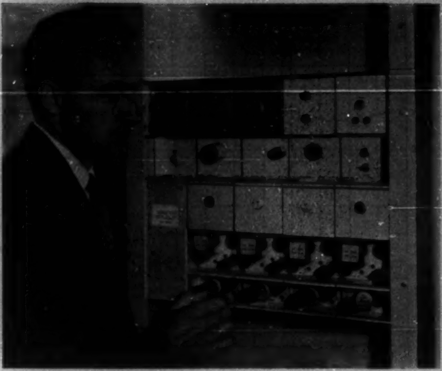

Fig. 8. View of terminal equipment

LINE FILTER EQUIPMENT

Line filters are injected at repeater and terminal points to separate the present 35-kc systems from the new *45CB* channels. They are designed to carry both the carrier and voice channels below 35 kc, and to accommodate both phantom and telegraph operation. Unusually sharp cutoff filters are provided through use of carbonyl powdered-iron cores. The low operating levels and the use of compandors in the system permit unusually small filters; both high-pass and low-pass line filters are contained in a single can of $7^{1}/_{2}$ by $3^{1}/_{2}$ by $3^{3}/_{16}$ inches. Two line filter sets for the two pairs of the phantom group can be contained within one pole-mounted filter housing, hung on the crossarm between the two pairs. A view of the pole-mounting line filter and housing is shown in Fig. 11.

The characteristic of the line filter is shown in Fig. 12. Reflection coefficient of the combined filter, directional filter, and terminal-repeater equipment is in the 10- to 20-per-cent range. Design was on the basis that, with compandors always required in the equipment, reflected near-end crosstalk will be at least 14 to 20 db below far-end crosstalk as contributed from each reflection point.

DIRECTIONAL FILTERS

Characteristics of directional filters are shown in Fig. 13. Both low-group and high-group directional filters are supplemented by an auxiliary directional filter operated at lower levels, with associated equalization for the combined directional filter complement and line filters. The mechanical arrangement of the directional filter is shown in Fig. 14. The larger can contains the directional filter for the two directions. The auxiliary filter and equalizer are contained in the next smaller can. The two smallest cans shown are for an annulling network for the nonflanked edges of the directional filter and for a repeater coil to provide balanced impedance to the high-frequency line. The combined equalized characteristic of directional filters, auxiliary filters, and line filters is shown in Fig. 15.

CHANNEL FILTERS

The design of the channel filters was simplified because of the use of a compandor to ease transmission requirements. A filter characteristic is shown in Fig. 16. Both transmitting and receiving filters of a channel are contained in a single plug-in unit, as with other *45*-class equipment. The channel units differ only as to which of four plug-in channel band filters are used. The equalization within the voice amplifier of the channel unit provides transmission channel characteristics comparable with those of other *45*-class equipment.

Use of Transistor Circuits in the 45CB System

The use of transistors in carrier telephone systems requires a design approach differing in many ways from that used for ordinary vacuum-tube circuit design. New parameters and terminology are necessary.

This section discusses at some length the problems encountered in the design of wide-band amplifier circuits and frequency-generating arrangements for the *45CB* carrier system.

It is assumed unnecessary to detail the fundamental manner in which transistors operate; however, certain of the terms which are used may require definition.

Briefly, the term α is a ratio of output to input current. β is a similar ratio of output-to-input current, with the circuit connected in common-emitter fashion. α and β cutoff are frequencies at which these respective current gain ratios are down 3 db. The term I_{c0} is the current flowing in the collector circuit with no bias between emitter and base.

TRANSISTOR CIRCUIT CONFIGURATIONS

Characteristics of the three commonly used transistor circuit configurations are shown in Table II. Space does not permit discussion of all of the circuits used in the *45CB* system. However, the transmitting amplifier of Fig. 17 is an example of a near-optimum combination of transistor arrangements.

Requirements for linearity, frequency response, load capabilities, impedance, and gain stability were quite rigorous. To achieve maximum power output with minimum distortion and good high-frequency response, the grounded-base configuration became mandatory in the output stage. Because of the low input impedance of this configuration, a common-collector (CC) interstage amplifier was used. An additional 30 db of required gain for the circuit made it desirable in the first stage of the amplifier to use the high-gain capabilities of the common-emitter (CE) circuit.

In discussing transistor circuits, it is convenient to make a comparison with familiar vacuum-tube circuits. However, because the input and output circuits are not isolated and because of the internal resistances of transistors, the internal feedback generated tends somewhat to modify and complicate circuit behavior. If the transistor is considered as a vacuum tube that always draws grid current and has resistances between all elements, then the analogy is valid.

The CE configuration is similar to the commonly used driven-grid circuit. Of the three configurations of Table II, it yields the highest power gains. Such an arrangement is shown in the input stage of the *45CB* transmitting amplifier; see Fig. 17. Gain in this circuit is expressed mathematically as in the following (assume generator is matched to transistor input).

$$\text{Power gain in db} = 20\ (\log\ \beta_2) + 10\ (\log\ R_L/R_I)$$

where

β_2 = current gain with load connected
R_L = load impedance
R_I = transistor input impedance

With transistors of present design, power gains of about 35 db can be obtained in practical CE circuits. Input impedance is a function of α and load impedance, and may be in the order of magnitude from 500 to 1,000 ohms. Output impedance is somewhat dependent on the internal parameters and the generator resistance R_G. A typical figure is 50 kilohms. High-frequency performance and distortion performance for the CE circuit are not as good as for the common-base (CB) configuration for the following reasons: in the CE connection, the upper frequency limit is $\beta_{\text{cutoff}} = \alpha_{\text{cutoff}}\ (1-\alpha)$, and directly α_{cutoff} in the CB arrangement. Since α is usually between about 0.95 and 0.99, the current gain will drop off much more rapidly for the CE connection.

Fig. 18 shows the collector-current characteristics V_c/I_c for the CE and CB configurations using a silicon transistor. These curves show that for minimum distortion at maximum power output, the grounded-emitter configuration is poorer than the grounded-base circuit.

The CB configuration used in the output stage of the amplifier in Fig. 17 is not only best suited where optimum power and distortion characteristics are required but also where the transistor is a limiting factor for high-frequency response. Some of the disadvantages of the CB configuration are low input impedance (30 ohms is typical) and relatively low gain. Although gain equations for the CB configuration indicate theoretical possibilities as good as the CE configuration, in practice this is not so. To achieve maximum gain, the load resistances assume impractical proportions. Further, to realize the low-distortion capabilities, emitter distortion must be minimized in both direct and feedback signal paths by using a generator impedance considerably

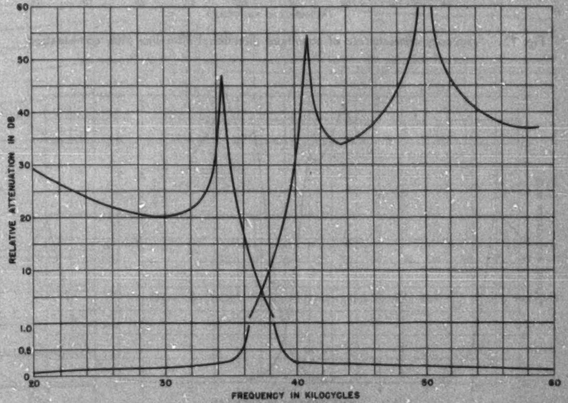

Fig. 12. Line filter attenuation characteristics

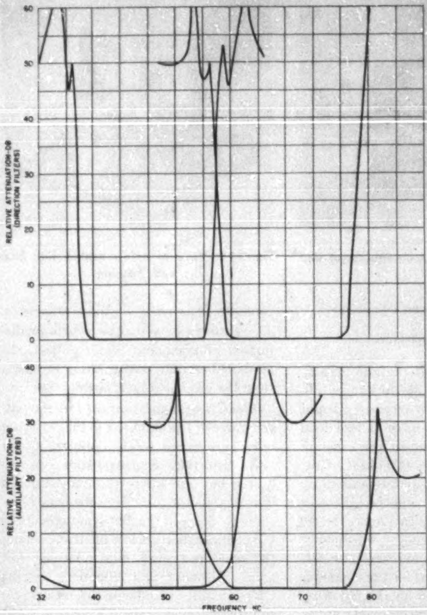

Fig. 13 (left). Directional filter attenuation characteristics

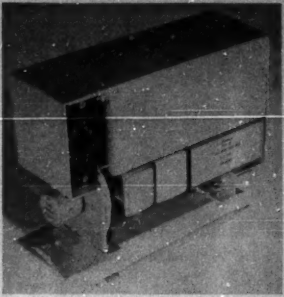

Fig. 14 (right). Plug-in directional filter unit

higher than the input impedance of the transistor. This causes a consequent loss in gain because of voltage division between the generator and the transistor. A typical gain figure is 20 db.

The CC circuit shown as the second stage of the amplifier in Fig. 17 is useful principally as an interstage device when connecting to a CB power stage or when operating into a low-impedance load. This circuit provides the lowest power gain of all three configurations (about 10 db). High-frequency and distortion characteristics are similar to the CE stage, except that maximum power output is limited by the permissible emitter voltage swing. For a particular transistor, the maximum power output is generally lowest for the CC configuration.

Temperature Considerations

The transistor is inherently a temperature-sensitive device. In germanium, the internal parameters vary considerably at rather moderate temperatures. In present germanium transistors, maximum operating temperatures occur somewhere between 50 and 70 degrees centigrade (C), allowing, of course, for a reasonable amount of power dissipation. Although the internal parameters for silicon also vary with temperature, the higher junction temperatures permissible (150 C) and a lower I_{c0} allow for sizable dissipation at ambients exceeding 100 C.

To achieve the circuit stability required in carrier design, compensation is necessary for temperature effects on both the d-c operating point and the a-c gain. In the amplifier shown in Fig. 17, this stability is attained by application of both a-c and d-c negative feedback. The a-c feedback circuits will be discussed in the following paragraphs. A typical d-c compensating network is formed by resistors R_1, R_2, and R_3 in Fig. 17. The transistor in this circuit is connected for

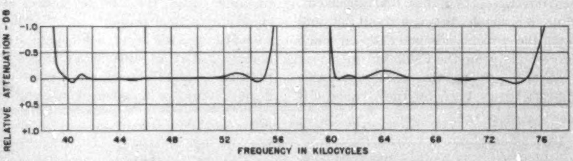

Fig. 15. Frequency characteristic of equalized directional filter–line filter combination

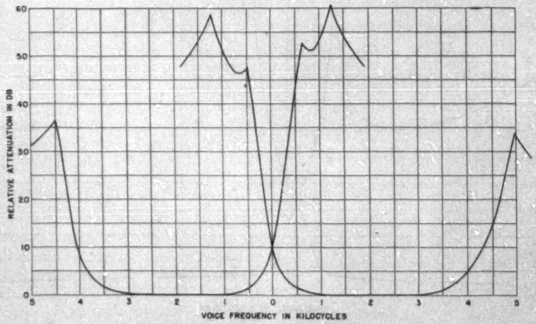

Fig. 16. Channel band filter attenuation characteristic

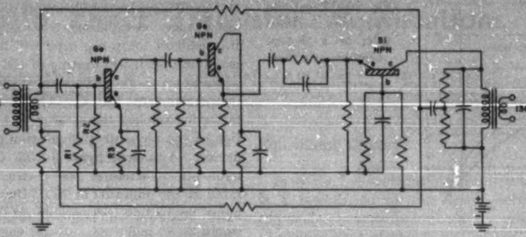

Fig. 17. Three-stage transmitting amplifier using transistors

Table II. Characteristics of Configurations

Circuit	Gain	Input Impedance	Output Impedance	High-Frequency Performance	Distortion	Tube Analogies
Common emitter (CE)	high	medium	medium	fair	poor	driven grid
Common base (CB)	medium	low	high	good	good	grounded grid
Common collector (CC)	low	high	low	like CE	fair	cathode follower

CE operation, which, as previously mentioned, is analogous to the driven-grid vacuum-tube circuit with a phase turnover of 180 degrees. Therefore, resistor R_3 is roughly equivalent to a cathode bias resistor and introduces stabilizing degeneration to the circuit. Because this resistor is by-passed by a rather large capacitor, the circuit is not degenerative at signal frequencies. Resistors R_1 and R_2 form a voltage-divider supplying battery potential between base and emitter to obtain the desired static operating currents. R_3 is made large compared with the emitter, base, and collector resistances and R_1 and R_2 are selected to provide a potential slightly higher than the voltage drop across R_3 at the proper emitter current.

The effectiveness of the temperature-compensating measures can be seen in Fig. 19, which shows gain and distortion for the amplifier. Note that gain is virtually constant for temperatures considerably in excess of 50 C, and that distortion variation is negligible.

FEEDBACK CIRCUITS

The entire amplifier of Fig. 17 is enclosed by a feedback loop. Although negative feedback is quite common in vacuum-tube circuits for carrier systems, the requirements are much more stringent when designing with transistors. Not only is the input impedance low as compared with vacuum tubes; but it is quite a variable from transistor to transistor and is subject somewhat to fluctuations of temperature and power supply. This, of course, is also true of the output impedance of the transistor. Furthermore, when designing high-frequency broadband equipment, the effect of the α or β cutoff and the attendant phase shifts must be carefully considered.

To achieve gain stability, flatness of frequency response, accuracy and stability of transmitting impedance, and low distortion, it is necessary to use relatively large combinations of both series and shunt feedback. The problem of matching the output stage to the load is similar to that encountered in a pentode tube. With the CB configuration, the output impedance is quite high, approaching one megohm; and for the CE configuration, is somewhat higher than the optimum load resistance. Therefore, it is necessary in the output stage to use a combination of series and shunt feedback (series raises the impedance; shunt reduces it), so proportioned that the desired net feedback is obtained with a matched-generator impedance. To obtain precision control of this impedance independent of transistor

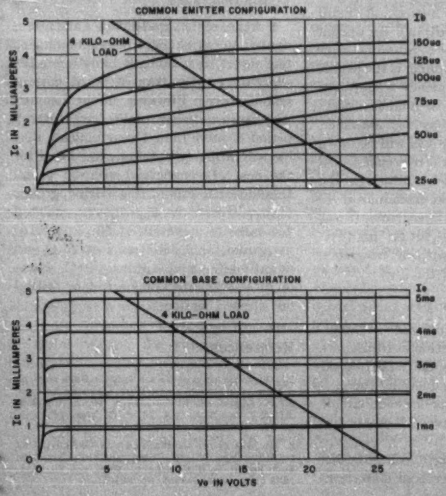

Fig. 18 (left). Static characteristics of CE and CB silicon transistor

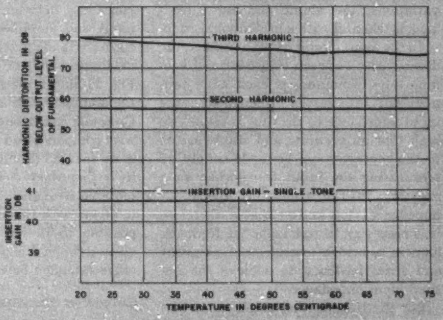

Fig. 19 (above). Effect of temperature on transistor amplifier gain and distortion characteristics

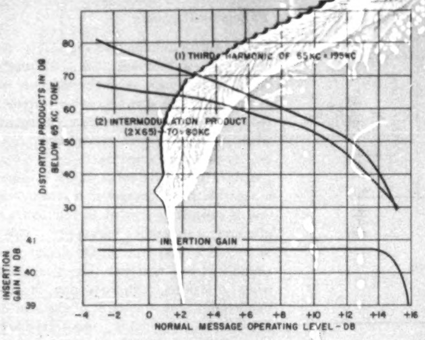

Fig. 20. Load and distortion characteristics of a 3-stage transistor amplifier

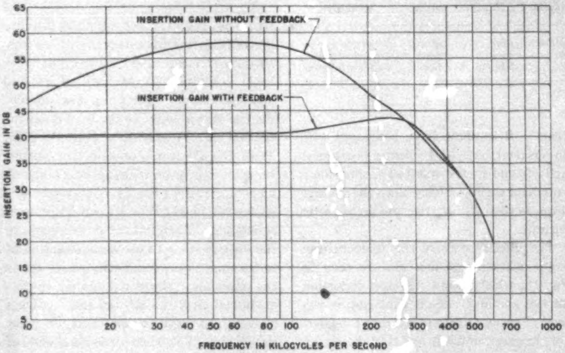
Fig. 21 (below). Frequency characteristic of a 3-stage transistor amplifier



variations, the shunt and series feedback is taken off with a bridge connection.

In the input circuit of the amplifier, the dissimilarity between transistor and vacuum-tube techniques is even more pronounced. At carrier frequencies, the input impedance to the tube is usually so high that an accurate and stable match to the generator can be made simply by terminating the input transformer in a resistor. In the transistor, the input impedance is low and a variable; therefore it is necessary to terminate the feedback loop in a bridge arrangement of shunt and series feedback to achieve the desired input impedance.

For the transmitting amplifier of Fig. 17, the input and output impedances are constant within ±5 per cent for any statistical distribution of transistors within the manufacturer's specification and over the entire termperature range from -20 to $+60$ C. Fig. 20 shows the load characteristics and some of the distortion products for this amplifier. Since the amplifier is operated at zero message level (zero loss between a 2-wire toll-circuit input and amplifier output), its output capacity is adequate for tone and message loading to which the amplifier is subjected. Fig. 21 shows the frequency response of the amplifier with and without feedback. Crosstalk contributed by the amplifier, with compandor advantage, will be down more than 65 db below a reference signal in a disturbed channel. Although the required frequency band extends from 40 to 76 kc, with the aid of feedback, it was possible to design for future high-frequency applications with a frequency range extended beyond 150 kc.

CHOICE OF TRANSISTORS

The carrier design engineer has available a rather large selection of transistors of the germanium types, and a fairly good selection in silicon. In choosing the particular type of transistor for each circuit of the *45CB* system, several factors were considered.

In power output stages, collector dissipation, ambient temperature, distortion, and frequency characteristics are of prime importance. A typical germanium power transistor of the p-n-p type will have a maximum dissipation rating of 150 milliwatts at 25 C, and a maximum junction temperature of 100 C. The derating factor for ambient temperature is a function of the physical configuration of the device. A typical figure is 0.5 C per milliwatt. Therefore, for a transistor rated at 150 milliwatt at 25 C, the maximum dissipation permissible at 60 C would be 80 milliwatts. Good engineering practice indicates that the transistor should be operated at approximately 50 per cent of rated dissipation at 25 C, providing maximum junction temperature is not exceeded at the extremes of operating ambient temperature. The output stage of the amplifier, shown in Fig. 17, required a dissipation of 80 milliwatts at 60 C, with an α cutoff beyond 1 megacycle. These requirements can be met at present only with silicon transistors. For driver stages, several germanium types are available. Although both p-n-p and n-p-n small-signal transistors can be obtained with α cutoffs considerably in excess of 1 megacycle, the p-n-p types tend to have considerably greater collector capacities, and, therefore, are not as well adapted for use in broad-band high-frequency amplifiers. Use of p-n-p transistors is therefore limited to amplifiers in the audio- or low-carrier-frequency spectrum, although they can be used quite successfully in oscillators to frequencies of 100 kc or higher.

LIFE EXPECTANCY

Because of the rapid advance and attendant frequent changes in manufacturing techniques, it is difficult to estimate life expectancy with transistors of current manufacture. However, in the Lenkurt laboratories, transistor life tests over a period of more than 1 year indicate that life will probably equal or exceed that for the best of commercial vacuum tubes. In additional tests at this writing, groups of transistors of five types have completed 4 months of operation at 50 per cent of maximum rated dissipation at 25 C and at an ambient temperature of 40 C. None of these transistors has failed or drifted out of specification.

Synopsis: A field effect transistor[1] is a unipolar device, distinguishable from a junction transistor in the following two ways: 1. the current flow is carried predominantly by one type of carrier alone; and 2. the electric field intensity is relatively high, thus the current flow is caused by field drift instead of by diffusion. Fig. 1(A) shows the construction of a field effect transistor. It consists of a piece of *n*-type germanium or silicon slab with a *p*-type junction formed around the center of the slab. Two ohmic contacts are placed in the vicinity of the junction. Three electrodes are connected to the transistor. The electrode connected to the junction is called the "gate." The electrodes connected to the ohmic contacts are called the "source" and the "drain." Five papers have already appeared on the field-effect transistors[1-5] in which the design theory, their experimental verification, the d-c equivalent circuit, and the estimate of the maximum cutoff frequency were presented. This paper describes an a-c equivalent circuit of the field effect transistor; the measured parameters of a type of germanium field effect transistor, and some of its circuit applications, with emphasis on oscillators and switching circuits. Special features of a field effect transistor with cutoff frequency near 5 mc (megacycles) are also presented.

D-C Characteristics

THE dependence[1,3] of the drain current on the drain and gate voltages is shown in Fig. 1(C). When a positive voltage is applied to the drain, with the source grounded, a current will flow from the source to the drain. If a negative voltage is applied to the gate, the drain current will decrease due to conductivity modulation.

When the magnitude of the gate voltage is increased to the pinch-off value W_0, the electron current will cease to flow, and the drain current is essentially the leakage current of the *pn* junction. On the other hand, if the gate voltage is kept constant, the drain current will increase with the drain voltage until a certain drain voltage is reached. After that, for further increase in drain voltage, the current remains relatively constant, indicating a high output impedance. It is to be noted that the gate voltage should always be kept negative; otherwise, excessive currents will flow, causing damage to the transistor. This is similar to the positive grid current of a vacuum tube.

Equivalent Circuit

Since the fundamental transistor action is a modulation of the drain current responding to a change in the gate voltage, the active part of the transistor can be best described by a transadmittance. This suggests an a-c equivalent circuit as shown in Fig. 2. It consists of the parallel combination of a passive, reciprocal network with elements y_{11}, y_{12}, y_{22} and an active current generator $(y_{21}-y_{12})v_G$. The relationship between drain and gate voltages and currents is:

$$i_G=y_{11}v_G+y_{12}v_D$$

$$i_D=y_{12}v_G+y_{22}v_D+(y_{21}-y_{12})v_G$$

The y parameters are complex, and change with frequency. They are measured by using a Tektronix *535* dual-beam scope, with the d-c bias kept at a drain voltage of 60 volts and a drain current of 5 milliamperes. (Because of high impedance levels, the y parameters cannot be measured accurately by a *GR* radio-frequency bridge. A detailed measuring technique is described in Appendix I.)

The results of the measurement of the conductance matrix elements are shown in Fig. 3. We can see that g_{11} decreases with frequency. Since g_{21} is essentially the transconductance of the active generator, it shows the frequency response of the transistor. g_{12} is negative and is smaller in magnitude than g_{11} and g_{22}. This ensures that the network consisting of y_{11}, y_{12}, y_{22} is a passive network. The measured results of the susceptance matrix elements are shown in Fig. 4. The fact that b_{12} is negative, and that the magnitude of b_{12} is less than b_{11} and b_{22} indicates that the susceptances are capacitive. When these matrix elements are combined, the passive network formed by y_{11}, y_{12}, and y_{22} can be reduced to an R/C (resistance-capacitance) network as shown in Fig. 5. The interelectrode capacitances C_{gs}, C_{gd}, C_{ds}, remain practically constant over the entire frequency range. For the transistor studied, C_{gs} is about 23 $\mu\mu f$ (micromicrofarads), C_{gd} is only 3 $\mu\mu f$, and C_{sd} is about 33 $\mu\mu f$. However, the resistances decrease with frequency. These decreases are probably due to the distributed nature of the device. The variation of the transadmittance y_m is also plotted in Fig. 5. It may be seen that the 3-decibel point, at which g_m equal b_m, occurs around 4.5 mc. This does not represent the highest frequency characteristics obtainable for a field effect transistor.[4] On the other hand, it represents the characteristic of a typical transistor fabricated, which has a reasonable cost and yield. If the physical dimensions of the transistor are reduced, the frequency response of the transistor can be improved at the expense of reduction in power rating and increase in cost. The maximum frequency of oscillation for a typical transistor described is around 10 to 12 mc. The input resistance remains relatively high, up to 500 kc. Beyond that frequency, the resistances decrease rapidly from several hundred thousand ohms to several thousand ohms. The results indicate that within a certain bandwidth the elements can be approximated by a constant R/C network, with the resistance taking a value at the center of the frequency band. This approximation results in great simplicity in the amplifier, oscillator, or other circuit designs.

Colpitts Oscillator

To illustrate the use of the equivalent circuit, a class-*A* Colpitts oscillator is designed. The objective is to design the tank circuit according to a specified frequency of oscillation and to predict the voltage swing and power output from the value of the load resistance. A schematic diagram of the oscillator is shown in Fig. 6.

By making use of the equivalent circuit, the loop equations for the circuit may be written. The determinant of the simultaneous equation is set to zero, some terms are neglected, and the conditions of oscillation are obtained; see Appendix II.

$$f\doteq\frac{1}{2\pi}\sqrt{\frac{C_d+C_g}{C_dC_GL}}$$

$$g_{11}\left(\frac{C_d}{C_g}\right)^2-(g_{21}+g_{12})\frac{C_d}{C_g}+\left(\frac{1}{R}+g_{22}\right)=0$$

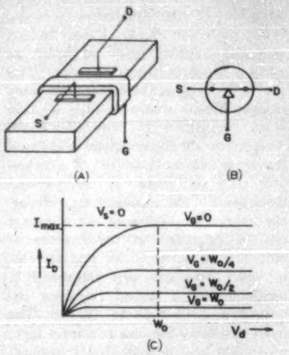

Fig.1 A—Field effect transistor. B—symbol. C—static characteristics

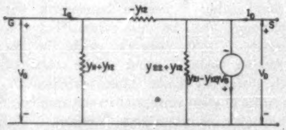

Fig. 2. Equivalent circuit of field effect transistor

From these two conditions, if one of the three tank circuit elements is chosen, the other two elements can be calculated. To check the accuracy of these conditions, experimental results have been compared to the calculated results. It is found that for $f=2$ mc and $L=140$ millihenrys, the calculated value of C_d/C_g is 0.63, and C_d equals 74 $\mu\mu f$. On the other hand, when the oscillator is tuned to 2 mc, the measured value of C_d/C_g is 0.618, while the value of C_d is found to be 60 $\mu\mu f$.

If it is recalled that the equivalent circuit is essentially resistive up to 2 mc, it is plausible that the power output and efficiency of an oscillator with an oscillating frequency less than 2 mc, can be directly predicted from the static characteristic curve as shown in Fig. 7. With the load resistance given, a load line may be drawn on the static characteristic curve. The load line intersects with the curves $V_G=0$, and $V_G=-33$ volts (the pinch-off voltage) at two points, giving two voltage swings. The smaller of the two swings is the drain voltage swing, v_D. From the voltage swing and load resistance the power output can be calculated. Since the d-c biases are known, the efficiency can also be calculated.

To verify the validity of these calculations, the power output and efficiency of a field effect transistor, the Colpitts oscillator is measured under the following conditions.

First, at a fixed bias point, $V_D=60$ volts; $I_d=6$ milliamperes, with the frequency of oscillation tuned to 2 mc; the load resistance has been varied from 2.2 K to 12 K. The measured and calculated results are found to be in good agreement, as shown in Fig. 8. This shows that for frequencies up to 2 mc, the amplitude of oscillation can be accurately predicted from the static characteristics. Furthermore, corresponding to each bias point, there is an optimum load to give maximum amplitude of oscillation. For the operating point of $V_D=60$ volts, $I_d=6$ milliamperes, $V_G=-12$ volts, the optimum load is about 6.2 K.

Second, the a-c power output and the efficiency of the oscillator are measured when the frequency is varied from 1 to 8 mc; see Fig. 9. With the operating point kept at $V_G=-12$ volts, $V_D=60$ volts and with a 6.2 K load resistance, the frequency of oscillation is tuned from 1 to 8 mc. It may be seen that when the frequency is higher than 2 mc, there is a decrease both in power output and efficiency. In other words, at frequencies higher than 2 mc, the power output and efficiency cannot be predicted directly from the static curves. The maximum frequency of oscillation for this circuit is found to be 11.5 mc.

Third, by maintaining a constant drain bias of 50 volts and a constant frequency of oscillation of 2 mc, the power output and efficiency are measured versus gate bias. (At each gate bias the load resistance is adjusted to the optimum value.) The measured results are compared with the calculated values in Fig. 10. As can be readily explained from the static characteristic curves, there is an optimum gate bias which gives maximum power output. This optimum bias occurs at $V_G=-12$ volts.

Fourth, when the transistor is operating at a constant gate bias, with the tank circuit tuned to a fixed frequency, an increase in drain voltage will shift the operating point to allow a larger amplitude of oscillation. Fig. 11 shows the measured and calculated power output and efficiency versus drain voltage with $V_G=-12$ volts, $f=2$ mc, and optimum load resistance.

From this study of the class-A oscillator, it is concluded that the tank circuit can be designed by the conditions of oscillation derived from the equivalent circuit. The power output and efficiency can be calculated from the static charac-

$$g_{11}\left(\frac{C_d}{C_g}\right)^2 - (g_{21}+g_{12})\,\frac{C_d}{C_g} + \left(\frac{1}{R}+g_{22}\right) = 0$$

Fig. 6. Colpitts oscillator

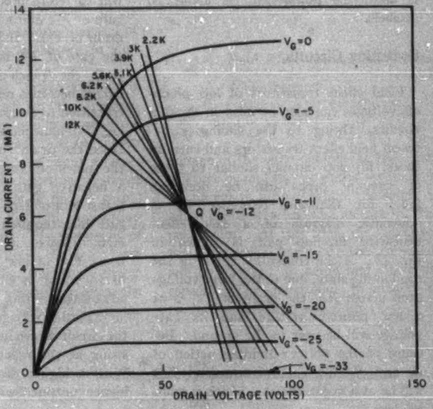

Fig. 7. Static characteristic

teristic if the frequency of oscillation is lower than 2 mc. This frequency is approximately one-half of the cutoff frequency at which $g_m = b_m$.

Power Rating

Although the highest power output data shown here is only 100 mw (milliwatts), output of more than 300 mw has been observed. The heat dissipation rating of the field effect transistors is 500 mw. If a class-*B* or *C* oscillator is designed, larger power output at 2 mc is possible. Furthermore, if the heat sink is improved, the same transistor could be made to dissipate 2 watts. This would make the field effect transistor unique in giving large output power at the range of 2 mc.

Neutralization

As shown in the equivalent circuit, the coupling between the gate and the drain is a simple parallel R/C combination. In a narrow frequency band, the inherent feedback caused by this R/C combination can easily be neutralized and unilateralized amplifiers thus achieved. (See, for example, reference 6.)

Application Utilizing High Input Impedance

The high input impedance of the field effect transistor makes it ideal in some applications, such as a preamplifier connecting to a high-impedance micro-

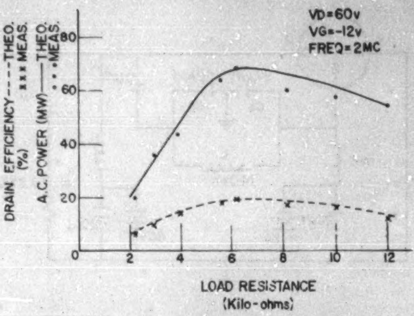

Fig. 8. Power output and efficiency versus load resistance

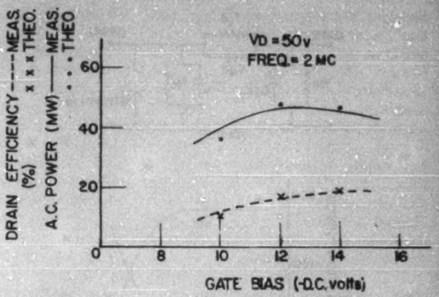

Fig. 10. Power output and efficiency versus gate bias

phone. However, in order to obtain reasonable efficiency, low pinch-off transistors are preferred (W_0 in the order of 10 volts). The typical input resistance ranges from 50*K* to 200*K*, the transconductance is about 500 micromhos. Thus, if a load resistance of 50*K* to 100*K* is used, the power gain is about 20 decibels.

Switching Circuits

Field effect transistors of low pinch-off voltages can also be used in flip-flop circuits. Owing to the similarity between field effect transistors and vacuum tubes, flip-flop circuits similar to those of vacuum tubes can be designed. (See, for example, reference 7.) A schematic diagram of a field effect transistor flip-flop pair is shown in Fig. 12. If the transistor *T*-1 is in the conducting state, due to the large voltage drop across R_{d1}, the drain of *T*-1 is at a low positive voltage and its gate voltage will be near to the ground. Because of the voltage-dividing action of R_1 and R_2, the gate of transistor *T*-2 will be at a negative value which is more than sufficient to pinch off transistor *T*-2. The drain of *T*-2 will therefore rest close to E_d, causing the gate of *T*-1 to rest near ground. This state is a stable one since small changes of the drain voltage of *T*-1 will not move the gate voltage of *T*-2 above "pinch-off," and will therefore produce no change at the gate of *T*-1 and no further change at the drain of *T*-1. If by means of a trigger, the gate of *T*-2 is moved more positive than the pinch-off gate voltage, the circuit becomes regenerative and a rapid transition to a second stable state occurs, i.e., *T*-1 nonconducting, *T*-2 conducting. Since the drain voltage is positive while the pinch-off gate voltage is negative, a negative gate bias is required. For transistors of high pinch-off voltage, the gate bias required will be unreasonably high. Hence, it is necessary to use transistors of low pinch-off voltages (10 to 15 volts) in a flip-flop circuit. One advantage of this flip-flop circuit is the large output voltage swing. For example, the circuit shown in Fig. 12 gives a 50-volt swing at the repetition rate of 100 kc. With a higher drain supply voltage, a higher output swing can be obtained. By replacing one of the feedback circuits by a capacitor *C* in the order of thousands of microfarads, the circuit becomes a monostable circuit; see Fig. 13(B). With an input pulse of 0.6 microsecond, the output pulse width varies with the value of *C* as shown in Fig. 13(A). A variation from 10 to 120 microseconds in pulse width is observed. The output voltage swing is about 50 volts.

When both feedback circuits are replaced by capacitance *C*, the circuit becomes a multivibrator. Due to capacitor coupling the negative gate bias is not necessary. The two diodes are placed to ensure negative gate voltage and to improve the wave form. The schematic diagram and the dependence of the repetition rate on the value of coupling capacitor are shown in Fig. 14.

Injecting Drain Transistor Circuits

Field effect transistors with a carrier injecting drain contact are characterized by a negative resistance region[3] in the gate input resistance curve. With the use of this property, bistable circuits, sine wave oscillators, relaxation oscilla-

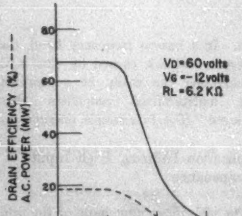

Fig. 9 (left). Power output and efficiency versus frequency

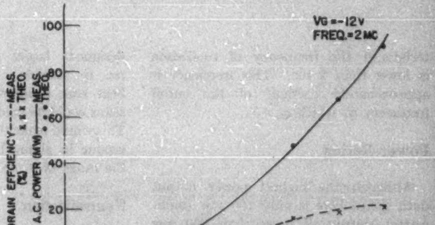

Fig. 11 (right). Power output and efficiency versus drain bias

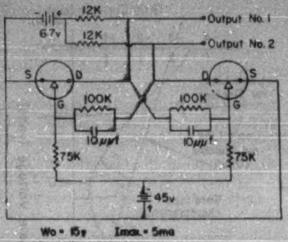

Fig. 12. Field effect transistor bistable circuit

tors, and monostable circuits similar to the point contact transistor switching circuits may be designed.[8,9]

A circuit diagram of such a bistable circuit is shown in Fig. 15(A). The drain is biased positive. If the gate terminals *GG'* are taken as the input terminals, a point-by-point measurement of the gate voltage and current characteristic can be obtained. A typical characteristic is shown in Fig. 15(C). (It has been pointed out that in the positive gate voltage and current quadrant, the characteristic would be similar to that of the double-base diodes.) It has three regions of operation: one positive low-resistance region, one negative resistance region, and one positive high-resistance region. It becomes apparent that if a proper gate load line is chosen, as shown in Fig. 15(C), three points of operation will be obtained. Among these points, *A* and *B* are stable points while *C* is an unstable point. At point *A*, the transistor is in the ON state with both the drain and gate currents large. At point *B* the transistor is in the OFF stage with both the drain and gate currents small and the gate voltage close to $-E_{G1}$. The OFF gate voltage will be dependent on the transistor characteristic. To modify this, a diode *D* is used which clamps the gate voltage to $-E_{G1}$, and the OFF point is raised to point *B*. A positive voltage applied to the gate will switch the transistor from the OFF to the ON state. A negative voltage applied to the gate will switch the transistor from the ON to the OFF state The source load resistance is included so that the bistable circuit can be triggered at the source to obtain better trigger sensitivity. The maximum switching rate of this circuit is 25 kc. The trigger sensitivity is poor because of the large pinch-off voltage of the experimental units.

When a parallel resonant circuit is used for the gate load, it presents a low d-c resistance. If the bias is selected properly, the d-c load line would intersect the gate input characteristic in the negative resistance region. Since this region is unstable, oscillation takes place. The highest frequency of oscillation is found to be about 300 kc. The output can be taken by inductive coupling to the tank circuit. The schematic diagram of a sine wave oscillator is shown in Fig. 15(B).

The source input characteristic is shown in Fig. 16. With this characteristic, a relaxation oscillator may be designed. First a load line is chosen which intersects with the input characteristic in the unstable negative resistance region. If a capacitor is placed across the source as in Fig. 16, relaxation oscillations will occur. The frequency of oscillation depends upon the R/C time constant. When the negative charge built up on the capacitor makes the source voltage more negative than the voltage of the valley point, the transistor will turn on and stay on until the capacitor discharges to a point where the source is more positive than the voltage of the peak point. At this time, the transistor will turn off. Once off, the capacitor will be charged up again and the cycle repeats. The maximum frequency of oscillation obtained was 6 kc.

Fig. 17 (right). A—Injecting drain field effect, transistor monostable circuit. B—Drain input characteristics and load line

The monostable circuit shown in Fig. 17 (A) is similar to the monostable circuit of a point contact transistor. The output pulse width is controlled by the input pulse width and amplitude. The transistor is biased in the OFF region by using a large drain load as shown in Fig. 17 (B). If no input is applied, the transistor will stay off. When a negative pulse is applied to the source which is larger than −3 volts, the transistor will turn on and stay on until the voltage on the source drops to a point where the gate diode is biased in the reverse direction, then the transistor will turn off and stay off until another pulse is applied.

Conclusions

An a-c equivalent circuit has been presented for field effect transistors on the admittance basis. It consists of the parallel combination of a passive R/C network and an active current generator. The values of capacitances remain relatively constant up to 5 mc while the resistances decrease with frequency. At frequencies less than 2 mc, the equivalent network is essentially resistive.

This equivalent circuit is used in the design of a Colpitts oscillator. The conditions of oscillation are derived by a circuit analysis, leading to the choice of the tank circuit. Experimental results are also presented on the oscillator performance under different operating conditions. It was verified that the a-c power output and efficiency of the oscillator can be calculated from the static characteristics even at frequencies up to 2 mc. The high dissipation rating of the field effect transistors make this type of transistor ideal for power oscillators in the frequency range around 2 mc.

Field effect transistors have high input impedances, especially for those with low pinch-off voltages. They are suitable for use in many applications, such as a preamplifier connecting to a high-impedance microphone, tuned or untuned intermediate-frequency or radio-frequency amplifier, cathode follower, and constant current device similar to a pentode. Since the feedback from the drain to the gate circuit is a simple parallel R/C network, neutralization can be realized easily.

Field effect transistors of low pinch-off voltage are also suitable for switching circuits. Since the electrodes can stand relatively high voltages (100 volts or higher), switching circuits can be designed to supply large voltage pulses. The design and circuit performance of bistable, monostable, and multivibrator circuits are presented. The trigger sensitivity is relatively poor compared to junction transistors. The maximum switching rate is about 100 kc.

Field effect transistors with a carrier injecting drain contact are characterized by a negative resistance region in its gate input resistance curve. With the use of this property bistable circuits, pulse amplifiers, relaxation oscillators, and sine wave oscillators with a single transistor in each circuit may be designed. The advantage of these circuits is their simplicity. However, due to the existence of minority carriers in this type of transistor the switching rate is much lower than that of point contact transistors.

In conclusion, the special features of field effect transistors are: 1. relatively high frequency of operation; 2. relatively high power rating, 3. high input and output impedance levels; and 4. high value of maximum d-c drain voltage. Because of these special features, field effect transistors are believed to be suitable for many applications in complement with junction transistors.

Appendix I. Measurement of Admittance Matrix Elements

Measurement of y_{11} and y_{22}

The signal generator is connected to the input terminal through a small current indicating resistance R. The output terminal is a-c grounded. Denoted by V_A and V_B the voltage developed across the two ends of the current indicating resistance is

$$y_{11} \text{ or } y_{22}=\frac{V_A\underline{/\phi_A}-V_B}{RV_B}-j\omega C$$

where ϕ_A is the phase angle of V_A with respect to V_B. The values of V_A, V_B and ϕ_A can be measured by using a Tektronix *535* dual-beam oscilloscope. C is the capacity of the scope lead across the input terminals. The value of R should be selected so that the real part of V_A is greater than twice the value of V_B. This eliminates the error introduced when subtracting two nearly equal quantities.

Measurement of y_{12} and y_{21}

The signal generator is connected directly to the input terminal. The output terminal is a-c grounded through a small current indicating resistance R. Denoted by v_C and v_D respectively, the voltages across the input and output terminals, are

$$y_{12} \text{ or } y_{21}=\frac{v_D-\underline{/\phi_D}\left(\frac{1}{R}+j\omega C\right)}{v_C}$$

where ϕ_D is the phase angle of v_D with respect to v_C. The values of v_C, v_D, ϕ_D can be measured by using a Tektronix *535* dual-beam oscilloscope. C is the capacity of the scope lead across the output terminals.

Appendix II. Condition of Oscillation for Colpitts Oscillator

The schematic diagram of the oscillator is shown in Fig. 6. The equation relating the gate and drain voltages are

$$(y_A+y_B)v_G-y_Av_D=0$$

$$[y_B+(y_{21}-y_{12})]v_G+y_Cv_D=0$$

where

$$y_A=-y_{12}-j\frac{1}{\omega L}$$

$$y_B=y_{11}+y_{12}+j\omega C_g$$

$$y_C=y_{22}+y_{12}+\frac{1}{R}+j\omega C_D$$

Thus, the condition of oscillation can be obtained by setting the determinant equal to zero

$$\begin{vmatrix} y_A+y_B & -y_A \\ y_B+(y_{21}-y_{12}) & y_C \end{vmatrix}=0$$

Equating the real and imaginary part of this equation to zero gives

$$\frac{g_{11}}{R}+g_{12}g_{11}-g_{21}g_{12}=(b_{11}b_{22}-b_{21}b_{12})+(C_gb_{22}+C_db_{11})-\frac{1}{\omega L}(b_{11}-b_{21}+b_{22}+b_{12})+\omega^2C_gC_d-\frac{C_g+C_d}{L}$$

and
$$g_{11}b_{22}+\frac{b_{11}}{R}+g_{22}b_{11}-g_{12}b_{21}-g_{21}b_{12}=\frac{1}{\omega L}\left(\frac{1}{R}+g_{22}+g_{12}+g_{11}+g_{21}\right)-\omega\left[g_{11}C_d+\left(\frac{1}{R}+g_{22}\right)C_g\right]$$

Numerical substitution for frequencies lower than 2 mc results in the following approximate equations

$$\omega^2=\frac{C_g+C_d}{LC_gC_d}$$

$$g_{11}\left(\frac{C_d}{C_g}\right)^2-(g_{21}-g_{12})\frac{C_d}{C_g}+\left(\frac{1}{R}+g_{22}\right)=0$$

IN THE fall of 1950, the University of Wisconsin began research in the design and construction of an automatic electronic digital computer to add to its servomechanism, analogue, and digital computer program. The project was undertaken for two reasons: 1. to obtain an additional research tool to supplement existing computing facilities such as the International Business Machines equipment operated by the university's numerical analysis laboratory and the electrical engineering department's high-speed electronic differential analyzer; and 2. to provide training for both students and staff in the problems of computer design, construction, maintenance, and use.

The essential features of the design were advanced by Amdahl.[1] As a result of an exposure to some of the early computers then operating at the Aberdeen Proving Ground, he became concerned over the bottleneck existing in the problem preparation phase of computing, and sought to incorporate in his design all possible features to simplify the operation of his machine from the user's point of view. His proposals were taken up by the department of electrical engineering and in the fall of 1950 the Wisconsin Integrally Synchronized Computer (WISC) was begun. A year and a half were spent in further study and design. No deadline for completion was set. The objective was to conduct a modest program of education, research, and construction, and to make the most of the opportunities for training young electrical engineers and acquainting them with some of the basic problems in this rapidly expanding area. Actual construction began in the spring of 1952, and now in the fall of 1955 testing and computing are alternately being carried on, and the WISC, Fig. 1, is about to begin its useful life. It is as far as known the only noncommercial large-scale computer built entirely without the support of the Federal Government.

Functional Design of the Computer

The computer itself is a fully automatic stored-program device of what is called intermediate speed. An over-all functional diagram is shown in Fig. 2. Like almost all such devices its information storage mechanisms are purely binary in character, and its internal arithmetic is therefore carried out entirely in the binary mode. Communicaton with the machine is by conventional decimal numbers, and conversion between binary and decimal is performed by stored subroutine.

In the early design stages considerable attention was given to the problem of speed versus complexity, and the apparent conflict between the goals of low cost and reliable high-speed operation. In particular it was recognized by Mr. Amdahl[1] that optimum performance would be obtained only when the speed capabilities of memory and arithmetic units were properly matched. Either performing parallel arithmetic operations on numbers stored on a relatively slow access drum, or combining serial arithmetic with a high-speed cathode-ray tube storage, would be an inefficient balance of cost of equipment versus speed of operation. Since over-all cost was an important consideration in this project, magnetic drum memory and serial arithmetic were chosen, but these were then carefully examined to determine the most efficient integration of their separate capabilities.

FLOATING POINT

As soon as operating experience with automatic computers began to be logged, it became apparent that the problems of fixed-point operation, which were relatively minor with hand-operated desk calculators, were tremendously magnified in automatic operation. So time-consuming did these scale factor adjustments become that a large number of computer users found it simpler and, in the long run, quicker to program the necessary steps to have the machine carry out all arithmetic operations in floating point, with automatic adjustment of the decimal point at each step, and to slow down the machine operating speed in favor of increased problem preparation speed. Such experience led to the decision to design into the WISC the additional circuits necessary to perform floating-point arithmetic automatically.

To the writers' knowledge, the WISC was the first electronic computer to propose such operation, and it is a decision which has never been regretted. The additional circuitry occupies perhaps 15 per cent of the computer, but the estimates of time saved by simplified programming range from 20 to 50 per cent of total problem time.

3-ADDRESS LOGIC

A 3-address logic was chosen for the WISC, since the word length needs to be great enough to include an exponent and its sign as well as the significant bits of a number with its sign. Whereas among experienced programmers the relative advantages of 1-, 2-, 3-, and n-address instructions will probably continue to be debated for many years to come, experience in the Wisconsin Numerical Analysis Laboratory strongly supports the contention that 3-address instructions are simpler to teach to beginning operators. As many people as possible should be able to use the WISC.

WORD STRUCTURE

With three addresses per order and floating-point notation in a number, the make-up of these two types of words presents a very good balance, as shown in Fig. 3. A number is represented as $\pm p \times 2^{\pm q}$, where p consists of 40 bits, q of 8, and 2 more are taken for signs. This converts at input and output into $\pm A \times 10^{\pm B}$ which is a 10-digit decimal number with an exponent range of $10^{\pm 75}$.

Paper 55-742, recommended by the AIEE Computing Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Fall General Meeting, Chicago, Ill., October 2-7, 1955. Manuscript submitted April 4, 1955; made available for printing November 7, 1955.

J. L. ASMUTH, C. H. DAVIDSON, J. B. MILLER, D. S. NOBLE, and A. K. SCIDMORE are with the University of Wisconsin, Madison, Wis.

The authors wish to express their appreciation to the entire staff of the Electrical Engineering Department, and particularly to its chairman, H. A. Peterson, without whose vision and understanding support the project could never have been carried through, nor indeed have come into being.

Fig. 1. The WISC

An order contains three 12-bit addresses, 4 bits to specify one of 16 fundamental operations, and 10 additional bits of which 6 are used only in an "extract" order. In either case, an additional 5 bits are allowed for switching time between words, making the total word length 55 bits. In the arithmetic operations the significant bits are separated from the exponent and signs, making a number composed of 40 bits plus 4 blank spaces. The lengths of these numbers are related by the cyclic memory requirement that forming 40 partial products of a 44-bit number takes the same number of digit times as storing 32 words each 55 bits long, 1,760 digit times.

Also shown in Fig. 3 is the order code for the WISC with an interpretation of the three addresses in each case. There are six arithmetic orders, eight orders which control the flow of computation, and one extract or logical multiplication order which allows the completely general modification of the contents of any register.

INTEGRAL SYNCHRONIZATION

In most fixed-point arithmetic, multiplication takes much longer than addition or subtraction, and division takes still longer. Consequently, it is common practice to sequence such a computer asynchronously, i.e., the successful completion of any one stage of the computation initiates the next. However, when the exponents have to be examined, the numbers shifted before and after adding, and the new exponent determined and formed, addition and subtraction times turn out to be more nearly equal to the times required for multiplication and division, and the gain in speed by asynchronous operation becomes much less. In fact, more time can be saved by making the maximum time necessary for any operation, arithmetic or otherwise, exactly the same, and by synchronizing all such operations with the memory cycle itself. In the WISC this works out in the following way.

As listed in the first column of Table I, a typical 3-address arithmetic order to the WISC requires that the following steps be performed:

1. The order must be located and read from the main storage. On the average this requires 1/2 memory cycle; to guarantee completion, 1 full cycle.

2. The addresses of the two operands *A* and *B* called for in the order must be located and their contents read. Since this is done simultaneously on two different readers, this requires an average of a 3/4 cycle, a maximum of 1.

3. The arithmetic operation on *A* and *B* called for must be carried out. For multiplication and division this has been adjusted to take 1 cycle. For addition and subtraction the time may be less but, to allow for the maximum amount of shifting in the worst case, nearly 1 full cycle is needed. One full cycle is allowed in all cases.

4. The result must be stored in the *C* address specified by the order. Time requirements are the same as in step 1.

To carry out any one order therefore takes 4 drum cycles on the WISC. However, since it can be guaranteed that each operation will be completed in the same time, all four operations can be carried out at once on four different orders. This procedure, called integral synchronization, results in the fourfold gain in speed shown in the remainder of Table I, and is the origin of the name Wisconsin Integrally Synchronized Computer.

One difficulty with the scheme shown in Table I was realized immediately, namely, the apparent impossibility of calling for the immediately preceding (or second preceding) result as an operand. However, a closer look at the timing shows that even this is possible by use of a special notation called short-memory coding.

The result of order n is guaranteed to be available from arithmetic by the end of cycle $n+2$. Although in the normal course an operand called for by order $n+1$ is located during cycle $n+2$, it is

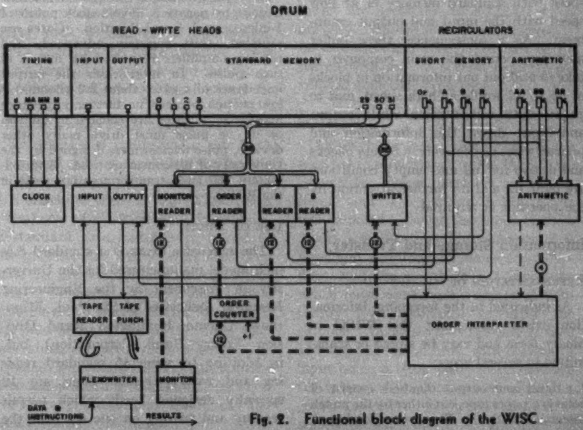

Fig. 2. Functional block diagram of the WISC

Table I. Integral Synchronization

Cycle No.	Order No.			
	n	$n+1$	$n+2$	$n+3$
n	Read order n			
$n+1$	Locate operands	read order $n+1$		
$n+2$	Perform arithmetic	locate operands	read order $n+2$	
$n+3$	Deliver result	perform arithmetic	locate operands	read order $n+3$
$n+4$		deliver result	perform arithmetic	locate operands
$n+5$			deliver result	perform arithmetic

not actually sent to arithmetic until the beginning of cycle $n+3$. Therefore, if the address of an operand in order $n+1$ is specified as short memory (binary 1000 0000 0000), the number emerging from the arithmetic recirculator *RR* at the beginning of cycle $n+3$ is returned immediately to arithmetic as operand *A* or *B*, as the case may be. Such special coding for preceding result has been used successfully in many computers, notably the card-programmed calculator.

If the result of order n is called for in order $n+2$, the machine finds itself trying to read and write in the same location during cycle $n+3$. This conflict is detected by the machine and a delay cycle is automatically inserted so that the result in question is first delivered, then located and used. Similar conflict detectors exist at other points in the machine's operation to eliminate the need for special attention to addresses by the coder; see section entitled "Reading Selector Circuits."

One additional logical feature deserves mention. Separate storage units of 32-word capacity each (subject to expansion) are reserved for input and output. These have additional circuitry associated so that they may communicate at high speed with standard memory or at slow speed with the input and output equipment. As a consequence, these buffer memories permit the main computer to take in and put out information in blocks of up to 32 words at high speed, and to go on with computation while output and input digest this information and prepare more respectively. Safety checks and delays for full and empty conditions are built in, and no further attention by the operator is required.

Information Storage and Transfer

REPRESENTATION OF "1" AND "0"

As indicated in the foregoing, information exists throughout the WISC in binary form and may be stored or transmitted in several ways:

1. Input and output numbers consist of holes in a paper tape, cut either by the punch associated with the Flexowriter keyboard, or by the punch attached to the output circuits themselves.

2. In the standard memory, information exists as magnetized cells on the surface of the drum, polarized one direction for "1," the opposite direction for "0." Not the least of the advantages of this type of storage is its nonvolatility with respect to power shutdown.

3. In electronic circuits information may exist or be transmitted in either of two forms: as one of two d-c levels, or as the presence or absence of a negative pulse at an expected time.

a. D-c information is obtained from the output of flip-flops used as storage, as counters, or as shift registers, or in special cases from manually set relays. Because of the very common use of a flip-flop output as a control voltage, the d-c levels at the plate of a flip-flop, +130 volts and +55 volts, are taken as a standard representation of "1" and "0," and manual inputs are converted to these levels for ease in combination. In this form, information can be used to control logical gates, to give visual information, or to control writing or punching operations. It has been found that in most cases the output of the triode flip-flop has a low enough impedance to permit direct coupling to the next stage; for control of more than one gate or for transmission to another chassis, the flip-flop is usually followed by a cathode follower.

b. Synchronization through the machine is done by negative 30-volt clock pulses of 1-microsecond (μsec) duration. Gates are sampled, shift registers advanced, and reading amplifiers reclocked by means of such pulses. In most cases the output impedance of a gate (about 2.2 kilohms) is low enough to need no further impedance matching; if gates are stacked in tandem or if one pulse must drive many other devices, pulse transformers designed by the University of Wisconsin are used. Approximately 260 such transformers are used in the WISC.

USE OF DRUM

The magnetic drum is a standard 8.5-inch model manufactured for the University of Wisconsin by the Engineering Research Associates of St. Paul, Minn. (now Univac Remington Rand Division, Sperry Rand Corporation), but, in addition to some 45 standard reading and writing heads, there are 12 specially designed heads which permit reading and writing on one track at the same time. Besides functioning as standard memory, the drum, as shown in Fig. 2, is used for input and output, for clock and timing tracks, for buffer storage between standard memory and arithmetic, and to provide a set of recirculating shift registers in the arithmetic operations themselves.

In a typical magnetic drum read-write head, both reading and writing windings are wound on one core, and either function can be carried on at any one time, but not both. In the special dual heads (Engineering Research Associates numbers *250A1* and *250B1*) a reading head is mounted 55 (in arithmetic 44) bits away from a writing head on the same track, and by means of elaborate shielding both operations can be carried on at one time, thereby allowing a single 55- (44-) bit word to be kept recirculating in this scratch paper or short memory.

These recirculators serve as buffers between standard memory and the arithmetic unit, between input and standard memory, and between standard memory and output, and perform the function of 55-bit static shift registers in each case. They are needed for such purposes as storing one operand until the second has been located, or for storing both until time for delivery to the arithmetic unit.

In the arithmetic unit itself, similar dual-head arrangements keep two operands and a result in constant recirculation with one additional modification. If the number being recirculated is read from the drum one bit early and passed through two stages of shift register, it can be tapped off from any of three different places to cause recirculation normally or with a shift right or left of one bit per recirculation cycle. Fig. 4 shows a dual head with its output fed back to its input through such a selector. This process can be extended as far as desired, which in the case of the WISC is two left shifts or four right shifts per cycle.

Structural Design of Computer

UNDERLYING PHILOSOPHY

The design of a complex piece of electronic equipment such as a digital computer admits a tremendous variety of possible detailed circuits for accomplishing specified objectives. A redeeming feature of this complexity, however, is the fact that even the most complicated circuit can be broken into large numbers of basic units or "building blocks" where the number of different types of such units can usually be made quite small. It was realized early in the WISC project that complex structure could only be

achieved by this procedure of assembling basic units, and that these units could be used as the basis for such building only after thorough design, analysis, and testing. Such a procedure reduces the number of uncertain elements in trying out any new circuit, and also greatly reduces the amount of "breadboarding" which is such a necessary part of electronic circuit design.

A second guiding principle was established in the matter of reliability. In spite of the desirability of small size and low number of tubes in any such computer, where the incompatability of these goals with the unquestioned need for reliability necessitated a choice, the choice was always made in favor of the more reliable circuit (where this could be determined).

Time constants must be carefully watched at all times, both to insure adequate recovery and to guard against the possibility of harmful oscillations when performing computations with unpredictable periodicities. In the same way, transformers and inductors must be critically damped or otherwise prevented from responding to any possible resonances.

One compromise with ultimate reliability (many are necessary of course in any realistic circuit) is the practice of using resistance-capacitance coupling to differentiate the output of one flip-flop into another. Although it is recognized that gating such a transfer of information would probably be more reliable, great circuit savings are gained, and the standard of operation achieved has justified the choice.

A compromise which has not been made is the practice of controlling a gate with a d-c level subject to change during the act of sampling. This can easily occur in a machine such as the WISC with several sets of clock pulses. Some early substandard gate pulses were traced to this practice and every effort has been made to prevent its occurrence, intentional or otherwise. Closely allied to this is the so-called suicide circuit in which a gate pulse shuts off one of the direct voltages which permitted its own generation. Although superficially this circuit appears to be self-protecting, unreliable operation of a sporadic nature may result, and the circuit has not been used.

FLIP-FLOP

The flip-flop used in the WISC is an essentially conventional Eccles-Jordan circuit, as seen in Fig. 5; the 1-kilohm grid resistor is added to suppress parasitic oscillations and is the only unusual feature. Since frequency requirements are eased by the relatively low 100-kc pulse rate, triodes with comparatively high grid circuit impedances can be used, effecting a significant economy in both number of tubes and power supply requirements. The circuit is a true trigger in the sense that the clock or gate pulse lasting less than 1 μsec initiates the transition, which is then maintained by the energy stored in the 50-micromicrofarad speed-up capacitors. The actual transition takes about 1.5 μsec; i.e., 1.5 μsec after the beginning of the initiating pulse, the plate of the side being cut off has achieved more than 95 per cent of its ultimate rise. To allow for loading effects and tube variations a minimum delay of 3.3 μsec before sampling the new information is maintained, or the state of the flip-flop is reversed.

In conventional or 2-input flip-flops, pulses are coupled in unilaterally by means of small capacitors to remove any inherent d-c bias. When flip-flops are coupled bilaterally, as in a counter, diode input coupling is used to prevent positive going transients from affecting the counter. Under these conditions the counter chains are sufficiently stable so that intermediate stages may be tapped to provide d-c input to gates or coincidence detectors without affecting the operation of either prior or subsequent stages.

All flip-flops and counters in the WISC use type-*6J6* tubes; where cathode followers are necessary, type-*12AU7* tubes are used. Should subsequent changeover be desired, these tube types can be replaced with any of several recently developed computer-type tubes.

GATES

Although d-c gates using crystal diodes are used to some extent in the WISC, the commonest logical operators are the 4-input "and" gates shown in Fig. 6. It will be noted however that three of these inputs are d-c enabling voltages of a level and character available from flip-flops, and the fourth is a 1-μsec pulse which must come from a source of sufficiently low impedance to drive the cathode. In most cases the gate is used as a 3-input logical unit, with the fourth input being a clock pulse to synchronize the information. The output of such a gate is a negatively going pulse of approximately the same magnitude and duration

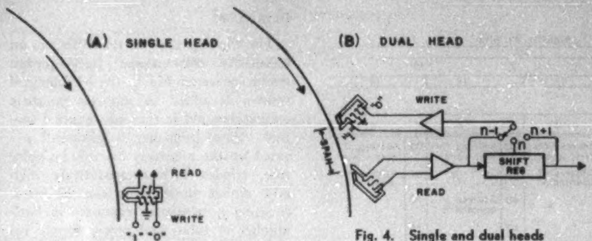

Fig. 4. Single and dual heads

as the clock pulse and, hence, is commonly used to set flip-flops and shift registers, and to drive counters. Upon occasion, however, when it is necessary to combine more than three inputs without additional delay, two gates may be stacked in tandem through impedance-matching pulse transformers. When so connected, the input pulse at the second cathode differs negligibly from a clock pulse.

As these gates are used, there is a similarity to the analogue or Kirchhoff adder in that one of four possible d-c levels may exist at the control grid of the gate. However the gate is always biased so as to pass a pulse only when all three inputs are high, for reasons which will be shown in the following.

Consider the three inputs A, B, and C in Fig. 6 as coming from the plates of three flip-flops. Each flip-flop may be at a potential of +130 volts (representing a "1") or +55 volts (representing a "0"). The control grid of the gate assumes the arithmetic mean of the three input levels and may, therefore, have a potential of +55, +80, +105, or +130 volts. If the cathode is normally biased at +150 volts but is driven down by negative 30-volt pulses, the cathode will be driven into the conduction region and the potential of the plate will drop accordingly, only if $ABC=1$. If only two of the three inputs are high, the grid will be at least 15 volts below the cathode at all times, which is well below cutoff. Gates with as many as five and even six such inputs were tested and found to operate quite well, but a maximum of three inputs was decided upon to reduce the need for critical control of pulse magnitudes, flip-flop loads, and the d-c gain of the cathode followers.

Now it is tempting to try to bias such a gate so that it will have the properties

$p(AB+BC+AC)=e$ (any two)

or even

$p(A+B+C)=e$ (any one)

This is dangerous, however, because of the variation in the static plate resistance of the side of the flip-flop under conduction with consequent variation in the output voltage achieved at the plate. *6J6* tubes as used in this circuit commonly range between 50 and 65 volts in this respect with occasional very good or very bad tubes giving values as low as 40 volts or as high as 70 volts. Consequently, if one or more of these conduction voltages is allowed to affect the grid control level which will permit a pulse to pass, variation with time and from tube to tube can seriously alter the discrimination of the tube and the quality of the output pulse.

Such a variation, however, does not occur in the plate voltage on the cutoff side, which is determined only by the potential divider effect of R_p, R_{pg}, and R_g. This voltage has been found to be constant at 132 volts with a fluctuation of less than 2 volts in the flip-flop circuit used, based upon approximately 100 measurements. If these voltages then are the only d-c levels which will enable the gate to pass a pulse, very high discrimination and very consistent output pulses may be obtained even with three inputs to a single gate. Where two gates are sampled with the same pulse, a *6J6* tube is used as a gate pair; if separate cathode pulsing is required, *12AU7* tubes are used.

D-c amplifiers, negators, and cathode followers of essentially conventional design also appear in the WISC, as do variations of a pulse amplifier which is used variously to supply clock pulses, to record on the drum, and to reshape other pulse information.

TIMING

The use of a magnetic drum as the principal storage and the gearing of logical and arithmetic operations to the speed of writing digits on the drum greatly simplifies one problem in that it removes the necessity of trying to synchronize the drum to an externally controlled frequency. All timing signals for the WISC, including the clock pulses themselves, are generated from reference marks recorded directly on the drum. If the drum speed should change within reasonable limits, all repetition rates change with it, and no harm is done.

Timing signals are distributed about the WISC in two ways, i.e., as negative going 30-volt 1-μsec pulses, and as d-c enabling voltages for gate control, lasting 1-digit time (10 μsec) or less. Since the source of clock pulses applied to the cathode of the gate must have high power and low impedance, these are generated in a special clock section and supplied to all sections of the computer at +150-volt bias.

Signals to mark other intervals are frequently wanted, however, and the following set is commonly available throughout the machine:

	Intervals, Digit Times	Pulses per Revolution
MA, minor arithmetic....	44	40
MM, minor memory	55	32
M, major	1,760	1

Pulses at *MA*, *MM*, and *M* times are needed less commonly and, in many cases, can be generated on the chassis where wanted by applying a d-c enabling signal to an unused gate tube or, frequently, to an unused input of the gate where the timing signal is being combined with other control information. Since advantage is taken of the five blank spaces between words to perform many different operations, several sets of *M* enabling voltages are available, occurring at slightly different times within this 5-digit time interval.

Although the pulse repetition rate is described as approximately 100 kc, as determined by the drum revolution rate, the use of pulse gates makes it highly undesirable to wait until digit time $n+1$ to sample conditions set up by digit pulse n if this can be accomplished sooner. It was mentioned in the discussion of flip-flops that it can be accomplished in less than 10 μsec; therefore, the time interval of 1-digit time has been broken into three approximately equal sections, and three complete sets or families of clock pulses called α, β, and γ are provided, approximately 3.3 μsec apart. This constitutes what is known as a 3-phase timing system. Note that on any one clock-pulse line, however, pulses still occur only every 10 μsec.

The interval of 3.3 μsec was chosen not only because it allowed adequate time for flip-flop transitions with a reasonable safety factor but also because it corresponds very closely with the inherent delay in writing, reading, and shaping of drum signals, thereby permitting writing pulses to be coincident with one of the families of clock pulses.

SHIFT REGISTERS

The shift register is a versatile device much used in computing machines, whether its elements are flip-flops, magnetic cores, ferroelectric cells, or any other form of binary storage device. Its functions are many and varied, and include storage, shifting (as the name implies), delay, and serial-to-parallel and parallel-to-serial conversion.

Information may be shifted down the line of a register by sequentially pulsing each stage if an adequately elaborate sequencing system, enough input connections, and sufficient time are available. Instead it is common practice to pulse the several stages simultaneously, and to cause the entire word stored in the register to advance at the same time. Such a procedure imposes an extra memory requirement, however, for the information in each stage (except the last) must be stored somewhere while the following stage is being cleared. This storage may consist of small capacitors, short-delay lines, or auxiliary flip-flop stages constituting a second register. The last of these techniques is in fact frequently used, and in elaborate circuits may be gated to permit bidirectional shifting.

Two types of flip-flop shift registers are used in the WISC. Where it is desirable that the information be available at all intermediate states of the register, conventional dual registers with capacitor coupling between the stages rather than gates are used. This circuit has the disadvantage, however, of requiring four half-tubes per stage.

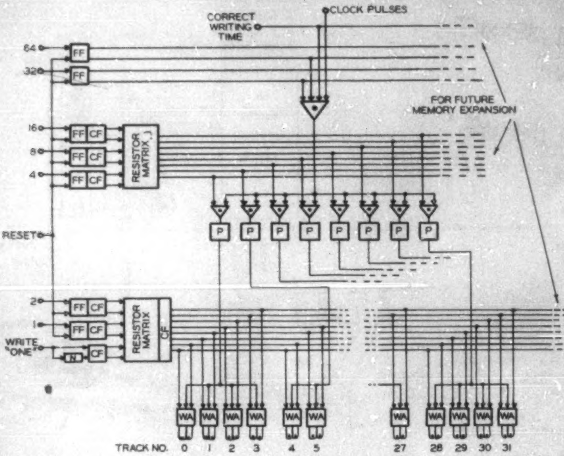

Fig. 9. Writing selector circuits

Where the output of the last stage is all that is desired, considerable saving in tubes can be effected by using the serial-parallel shift register, as shown in Fig. 7. Since the timing system in the WISC is 3 phase, as described in the foregoing, three different flip-flops can be pulsed sequentially in 1-digit time. Such a 3-stage register only shifts two different bits of information, however, since, upon completion of the third pulse (or any other), two stages contain the same information. As compared with conventional shift registers containing a complete set of temporary storage stages, a shift register of this type requires approximately 25 per cent fewer tubes.

Reading Selector Circuits

Fig. 8 shows the circuits used for reading out of the main storage section of the drum. The reading selection system must furnish four fully independent simultaneous outputs: one for reading the next order, two for locating the operands called for, and one for monitoring purposes. Although they are normally different words, any two or more of these outputs may be the same.

The selection of a desired word on one of the outputs is done in two steps: 1. the desired track on the drum is connected to that output; and 2. the correct word of the 32 is selected by its position in time measured from a mark pulse on the drum. Only that part of the circuit used for the track selection is shown in the figure.

The information written on the drum is amplified by a pentode preamplifier which, by using a transformer in the plate circuit, also accomplishes differentiation of the signal. These transformers have four secondary windings, one for each of the outputs. The d-c potentials on the return end of the individual secondaries are set by a selector matrix consisting of 160 resistors. Of a given set of 32 windings associated with an output channel, only one is at a level of approximately +130 volts. The other windings are from 15 to 75 volts below this level, with the result that only the signal which is biased at the high level appears at the output of the cathode follower.

This signal is then further amplified and, by means of a reclocking gate, is phase-detected and resynchronized. The desired word of those on a given track is selected by means of a coincidence detector which determines coincidence between the last five bits of the address of the word and a signal written on a control track of the drum which identifies each of the 32 angular positions of the drum.

The reading circuits must be capable of recovery from the very large signals caused by writing onto the drum within 40 μsec (4-digit times) to permit reading a word out of the next angular position. Simultaneous reading and writing on the same head (or even on adjacent heads) cannot, of course, be permitted, and detection circuits are built into the machine which allow an extra cycle of operation when such operation is called for in the programming. (This is another example of the design principle that the computer is to take as much of the burden as possible from the programmer.)

The monitor output is used to provide a visual display of the contents of any storage position independent of machine operation. In this case the desired track and time position are entered manually by means of switches, and programming is not necessary.

Writing Selector Circuits

The problem of the standard memory writing system is to select one of 32 tracks and, upon command, generate a writing pulse in either the "1" or the "0" side of the high-impedance writing coil in the head associated with that track. There are, therefore, seven pieces of binary information available as inputs: five to determine the track, one which selects the proper *MM* time, and one which controls whether the bit to be written is a "1" or a "0." The last of these must be capable of an arbitrary sequence of changes at 10 μsec intervals during writing.

The recording current pulses, supplied by *6AQ5* miniature beam power tubes, have a magnitude of 200 milliamperes for one μsec. Both "1"s and "0"s of a word are written but, because the track is saturated in the "0" direction, the readout signal for a "0" is considerably smaller than for a "1" and is, of course, of opposite phase.

Since one writing tube is connected to each half of the center-tapped write winding, there are 32 pairs of writing tubes required. The driving voltages for each pair of writing tubes are coupled from *6J6* pulse gates by means of 1-to-1 pulse transformers.

In the over-all block diagram of the standard memory writers and track selectors, Fig. 9, the pulse amplifiers *P* reshape and provide a low output impedance for the clock pulses which have already passed through two gates in tandem. The gate grid voltages are derived from resistor matrixes controlled by the binary track information in the flip-flops.

Coincidence Detectors

In the input-output section are six 5-bit parallel coincidence detector units, each consisting of a 5-stage binary counter and ten cathode-follower-driven diode coincidence detectors. These units are identical so that one spare unit serves for all. Three are used in input; three in output. In input, for example, one counter is used to indicate the *MM* position on the drum,

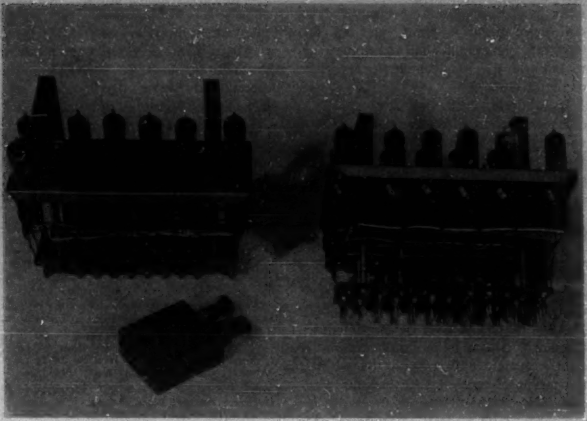

Fig. 10. Plug-in chassis

another to count the words read in from the tape to input memory, and the third to count the words delivered from input memory to standard memory.

When, and only when, all five pairs of bits of the two numbers being compared agree, coincidence is detected and a gate enabling voltage is made available through a cathode-follower driver to the appropriate gates, indicating that a word may be read in or out as the case may be.

The rise time of the gate enabling voltage from the coincidence detector is approximately 1 μsec which in most cases permits sampling one phase time (3.3 μsec) after the counter is advanced. However, in critically timed circuits, these gate enabling voltages are not sampled until two phase times (6.7 μsec) later to insure positive sampling.

Each coincidence detector unit employs 12 twin triodes: five in the binary counter, five as cathode-follower drivers to the coincidence diodes, one as a reset tube, and one as a combination negator and cathode-follower driver for supplying the coincidence gate voltage. In addition there are 20 type-*1N38* germanium diodes: ten for the coincidence detection, and ten for diode coupling in the counter circuit.

When the two numbers to be tested for agreement are in serial form, they may first be registered in a staticizer and the coincidence detector described in the foregoing may be applied, or a serial coincidence detector may be used. In such a device each of the two numbers is registered, bit by bit in time sequence, by a flip-flop. Each digit time these two flip-flops are examined for disagreement. If by the end of the interval of interest no disagreement has been detected, the two numbers must have been the same. Perhaps this device should be called an anticoincidence detector?

The detection of disagreement is accomplished by a pair of gates, one for each of the two ways in which a pair of binary digits can disagree. The two gates have a common output which is the input to a third flip-flop. At the beginning of the interval of interest this third flip-flop is reset, to be set only if there is a disagreement between a pair of corresponding digits.

This coincidence detector is capable of being tested for coincidence or lack of coincidence as soon as the last of the digits to be compared has been examined. The use of a parallel coincidence detector, in conjunction with a pair of shift registers to staticize the information, would not make coincidence information available any sooner, and would involve a substantially greater number of tubes, which would have to be increased with the number of digits in a number.

In addition to the four tubes constituting the serial coincidence detector, two timing signals are needed to mark the beginning and end of the interval of interest, one to sample the information in the flip-flop which records lack of coincidence, and one to reset this flip-flop. The number of tubes here is independent of the number of digits in a number.

PHYSICAL PLANT

As with most electronic devices of similar complexity, the use of small plug-in packages greatly simplifies construction and maintenance in the WISC. The size of these units represents a compromise between the opposing pressures of compactness and logical isolation. In the WISC, single and double chassis of 12 and 24 tubes respectively were decided upon, and these chassis have proved extremely flexible and convenient. Some experimental work has been done on a smaller 2-tube package designed by the University of Wisconsin, as shown in Fig. 10. These are intended to facilitate laboratory experiments accompanying course instruction, and to provide a 1-to-1 correspondence between circuit elements and a logical diagram in breadboard experimentation. The mechanical construction of these chassis (and indeed of all chassis, frameworks, cabinets, and mountings) was done by students or members of the university staff. There are 80 single and 14 double chassis in the computer circuits proper, in addition to 100 tubes in nonstandard chassis, such as power supplies, monitor facilities, etc. Altogether there are about 1,400 tubes in the WISC.

With the exception of the motor-generator set, the WISC is contained in four separate cabinets, each with its own heater supply and direct-voltage regulator units. The magnetic drum, the control circuits, reading and writing amplifiers, and the various clock pulse generators are located in the largest of these, which also houses master power switches and a running time meter. There are two small cabinets connected by cable to the large cabinet, one housing the arithmetic and the other the input-output circuits. The remaining cabinet is the operating console which contains the monitor, tape reader and punch, and associated controls.

Each cabinet has cooling blowers and is mounted on casters for flexibility in physical arrangement. The total floor area occupied excluding the motor-generator set is approximately 35 square feet.

Power is supplied to the machine from a 230-volt 3-phase line. The heater supply transformers in general have their secondaries isolated from one another so that heater-to-cathode voltages may be kept at a minimum in the various plug-in chassis by biasing the heater secondaries. Each cabinet has its own filament supply.

The direct current is supplied from a single motor-generator set which consists of one 3-phase driving motor and two d-c generators. One d-c generator supplies all of the positive-to-ground voltages and the other the negative-to-ground voltage. There are three positive voltages of +250, +150, and +130 volts respectively.

It has not been found necessary to regulate the +250-volt supply since it is used primarily in generating pulses. It is, however, supplied in isolated and filtered channels to the various logical units of the machine, the isolation and filtering being done as near as possible to the point of use. The +150-volt supply which is used as flip-flop plate supply, and which therefore furnishes critical control of gates, is electronically regulated with the use of conventional regulators so distributed that each supplies a small group of chassis. Eighteen such regulators are used in the complete machine, and give excellent isolation as well as regulation.

In regulating the negative 250-volt supply, conventional electronic regulators would prevent employing the same isolation scheme used for the +150 volts. The d-c generators are connected in a 3-wire system, and the common line is both direct current and signal ground. To achieve isolation, therefore, a series electronic regulator unit must have its regulator tube located in the minus line. The cathode of this tube must then be at a still more negative point, and special electronic bias supplies had to be provided to bias the d-c amplifier in the negative regulator circuits.

In addition, each section of the machine is supplied with a regulated +130-volt small-power supply line for additional gate bias purposes. The total power consumption of this machine is approximately 10 kw.

Results

In its nearly 5 years of operation, the digital computer project has paid off manyfold. A working computer of unique design has been developed, outstandingly simple to program, and sufficiently moderate in cost to be within the means of many institutions and organizations hitherto unable to justify a computer in its budget. Results in education and experience acquired have been invaluable. Formal training in both computers and computing has been provided in course instruction and graduate research. Some by-products of research have appeared as bonuses: a complete line of home-wound and potted pulse transformers, and several new types of plug-in package circuits for modular construction. Last but not least, the accumulated knowledge places the University of Wisconsin in a uniquely advantageous position for continued research in connection with computing machines, computer components, and computing in the years to come.

Transistor Analogue Computing Amplifiers for Flight Simulators

ROBERT C. WEYRICK
ASSOCIATE MEMBER AIEE

A WIDELY used flight-simulation method for flight trainers is the use of an analogue computing system employing a modulated 400-cycle-per-second (cps) carrier. A recent paper[1] described four basic computing components that have been developed for use in computing systems of this type. Two of these components are vacuum-tube amplifiers. These are: 1. a summing amplifier of the voltage feedback type having a 1-per-cent accuracy of summation; and 2. a power amplifier for servomotor operation. This paper describes the design and characteristics of two transistor amplifiers that are directly interchangeable with these vacuum-tube amplifiers.

Summing Amplifier

To provide for interchangeability and direct comparison, the performance requirements of the transistor summing amplifier are the same as those previously established for its vacuum-tube equivalent. These requirements are:

1. The amplifier should produce a balanced output of 25 volts rms across a load consisting of four 20,000-ohm potentiometers (two on each output) or a tuned resolver. This condition requires a power output of 125 milliwatts.

2. With the feedback resistor and each input resistor having a value of 500,000 ohms, the amplifier should sum a maximum of four inputs without introducing an error of more than 1 per cent. This condition requires a minimum effective gain of 40 decibels where effective gain is defined as the open-loop gain from one input to the output, and with the feedback resistor and the other three input resistors grounded through low-impedance sources.

3. The amplifier should remain stable when the shunt capacity of the resistive load is 0.001 microfarad or less for each potentiometer.

The schematic diagram of the transistor summing amplifier is shown in Fig. 1. Seven junction transistors are used.

In the design of the output stage, the desire for low-power consumption and high efficiency led to the choice of class-*B* push-pull operation. The availability of both n-p-n and p-n-p transistors made possible the use of complementary symmetry.[2] Basically, such an arrangement utilizes transistor characteristics whereby the input signal polarity which increases conduction in a p-n-p transistor is opposite to the polarity which increases conduction in an n-p-n transistor. The use of such a circuit eliminates the need for two inputs having opposite phase.

A grounded-base connection is used for output transistors *V1405* and *V1407* be-

cause it exhibits better linearity and d-c stability than a grounded emitter connection. A split-primary output transformer *T1401* is required since the supply voltages for n-p-n and p-n-p transistors are of opposite polarity.

The input resistance of a grounded-base stage is low, generally less than 100 ohms. Because of this low resistance, the output stages are driven by directly coupled, grounded-collector transistors to provide a relatively high input resistance and low output resistance.

With the output transistors operating class *B*, some distortion is present in the output wave form because of increased emitter resistance at low values of emitter current. This distortion is removed by biasing the output transistors so that their operation is slightly class *AB*. These bias resistors are *R1417* and *R1418*. Such operation results in a maximum collector dissipation of approximately 75 milliwatts.

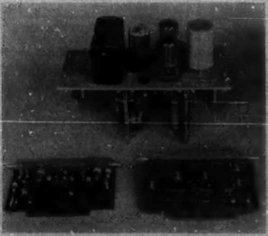

Fig. 2. Two views of transistor summing amplifier (bottom) and its vacuum-tube equivalent (top)

The two types of output transistors used in this stage are Texas Instruments type *X-2* (n-p-n) having a maximum dissipation of 100 milliwatts at 50 degrees centigrade, and Transitron type *2N43* (p-n-p) having a maximum dissipation of 90 milliwatts at 55 degrees centigrade.

The input transistor *V1401* is also wired as a grounded-collector stage to obtain a high value of input resistance at the summing point. This input resistance is approximately 200,000 ohms at 400 cps. Because of the low signal level at this stage, it was considered desirable to reduce the noise level. Since transistor noise increases with collector voltage,[3] the collector voltage of the input transistor was reduced to approximately 3 volts by a divider composed of *R1401* and *R1403*. The voltage gain of this input stage is very near unity. Transistors *V1402* and *V1403* are grounded-emitter stages and provide voltage gains of 17 and 4.5 respectively. The emitter resistors *R1407* and *R1413* provide a measure of gain stabilization.

Because of the large amount of negative feedback around the amplifier, stabilizing networks were necessary to prevent oscillation from excessive phase shifts at high and low frequencies. The high-frequency response of junction transistors is, in general, dependent on both collector capacity and alpha cutoff frequency. Grown-junction n-p-n transistors usually have both a lower collector capacity and a higher alpha cutoff frequency than alloy-type p-n-p transistors. More adequate high-frequency stabilization is therefore obtained from the n-p-n units.

Two phase-lag networks (*R1419*, *C-1404*) and (*R1415*, *C1408*) are included for high-frequency stabilization with a resistive load. The phase margin at high frequencies was further extended by bypassing the emitter resistor *R1413* with an 0.01-microfarad capacitor *C1407*. When the amplifier is used with the tuned resolver load, the network consisting of *R1419* and *C1404* is removed. Low-frequency stabilization is provided by a phase-lead network *R1411* and *C1403* connected between *V1402* and *V1403*.

Relays *K1401* and *K1402* are provided for test purposes. In the operating position, the input signal is connected to the amplifier. In the testing position a known 400-cps test voltage from the trainer is applied to the amplifier, and the feedback resistor is disconnected. This arrangement permits a measurement of the open-loop gain at 400 cps.

The d-c power requirements of the summing amplifier for an output of 125 milliwatts are ±22 volts at 9 milliamperes each, ±6 volts at 9 milliamperes each, and +30 volts at 3 milliamperes, or a total power requirement of approximately 0.6 watt. By comparison the

*C_s = shunt capacity across load.

power required for the equivalent vacuum-tube summing amplifier is 8.4 watts.

Different views of two transistor summing amplifiers are shown in the lower part of Fig. 2. Printed circuitry and miniature components were employed throughout. The upper part of Fig. 2 shows a unit containing two equivalent vacuum-tube summing amplifiers. Table I provides a physical comparison of these units. The performance of the transistorized summing amplifier was evaluated by comparing its characteristics with those of its vacuum-tube equivalent.

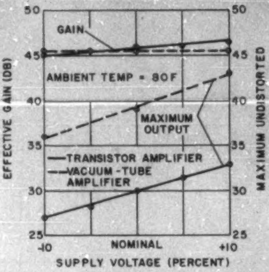

Fig. 3. Effects of supply voltage variation summing amplifier

Table II summarizes the significant points of the amplifier frequency response under various load conditions. At 400 cps the effective gain and the phase shift at a closed-loop gain of 1 are comparable in all uses. The phase and gain margins of the transistor amplifier are, in some cases, less than those of the vacuum-tube amplifier; however, they provide adequate stability against high-frequency oscillation.

Fig. 3 shows the effect of a ±10-percent variation of d-c supply voltage. The maximum undistorted output was determined under closed-loop conditions and a voltage gain of 1.

Fig. 4 shows the effect of ambient-temperature and humidity variations. The effective gain is shown as a function of ambient temperature and relative humidity at an ambient temperature of 90 degrees Fahrenheit. The gain of the transistor amplifier increases with increasing temperature. This gain change develops in the grounded-collector stages *V1404* and *V1406* and is caused by the operating point changing with temperature. This drift also affects the maximum undistorted output of the amplifier at temperature above 120 degrees Fahrenheit. At 130 degrees Fahrenheit, the maximum output

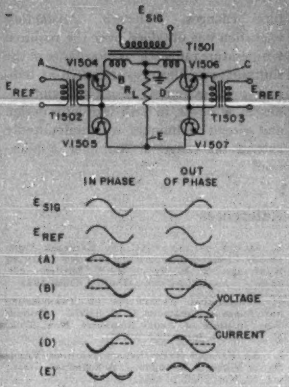

Fig. 6. Wave forms of transistor phase detector

drops from 29 volts rms to 23 volts rms. By comparison, the effects of temperature and humidity over these ranges on the vacuum tube amplifier are slight.

A number of transistors were substituted in the different amplifier stages to determine what effect transistor replacement would have on performance. The gain of the various stages (with the exception of the grounded-base output stages) was found to vary somewhat with the current gain $\alpha/(1-\alpha)$ of the transistor. The other transistor parameters emitter resistance, base resistance, and collector resistance had little effect on gain. Table III shows the effective amplifier gain at 400 cps when transistors having various current gains were substituted in the different stages, and when all voltage amplifier stages except the stage receiving the substitution retained original transistors having approximate current gains of 50 each.

Servo Amplifier

The performance requirements of the servo amplifier are also the same as for its vacuum-tube equivalent and are as follows:

1. The amplifier should be designed to operate a 5-watt servomotor.
2. The amplifier should sum a maximum of four inputs and produce a shaft rotation proportional to within ±1.0 degree of the sum of the inputs.
3. The frequency response of the output shaft should extend to 10 cps.

The transistor servo amplifier consists of a 3-stage voltage amplifier, a phase detector using four transistors, and a magnetic amplifier output stage. A full-wave rectifier and filter are added to the amplifier circuit to provide direct-voltage supply. The over-all schematic diagram of this amplifier is shown in Fig. 5.

Fig. 7. Assembled transistor servo amplifier

The function of the amplifier section is to amplify the resultant voltage of the various signal inputs to a level suitable for the magnetic amplifier input. The input stage is similar to that of the summing amplifier. Transistor *V1501* is connected as a grounded-collector stage to obtain a high input resistance, and the collector voltage is reduced to 5 by a divider composed of *R1502* and *R1504*. Transistor *V1502* is emitter-grounded, and resistance-capacitance-coupled to the input stage. The voltage gain of this stage is approximately 7.

Transistor *V1503* is also a grounded-emitter stage, and its output is transformer-coupled to the phase detector. The maximum undistorted output is 11 volts rms. To maintain this value, the d-c operating point is stabilized by the addition of *R1511* in the emitter circuit. This resistance is by-passed for 400 cps by *C1506*.

Negative feedback is added around the transistor amplifier through resistors *R1512*, *R1513*, and *R1501*. The primary purpose of this feedback is to lower the effective output impedance of the amplifier from about 16,000 to 2,500 ohms. This lower value of output impedance increases the effectiveness of the lead network *R1520* and *C1509* in the magnetic amplifier control winding. This negative feedback, also stabilizes the amplifier gain when transistors are replaced by units having slightly different characteristics.

The function of the phase detector is to convert the a-c output of the transistor amplifier to a polarity-reversing d-c input for the magnetic amplifier. This phase detector employs transistors *V1504*, *V1505*, *V1506*, and *V1507*. The use of transistors for this detector provides two advantages over a diode-bridge type of detector. Since there is no large circulating current through the transistors, no offset or unbalance can develop, and the amount of reference power required is appreciably less.

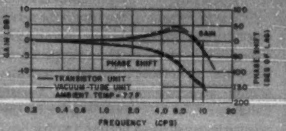

Fig. 8. Frequency response of positional servo system

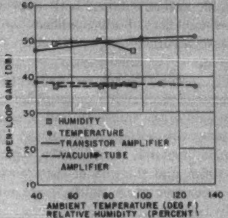

Fig. 9. Temperature and humidity effects, servo amplifier

The operation of the transistor phase detector is shown by the wave forms in Fig. 6. The 400-cps reference voltage is supplied to the emitters through step-down transformers *T1502* and *T1503*. These transformers are phased so that forward emitter current flows in *V1504* and *V1505* during one half-cycle and in *V1506* and *V1507* during the other half-cycle (wave forms *A* and *C*). The collectors of each pair of transistors are connected in series. During a half-cycle of forward emitter current the two paired transistors present a low-resistance path from the secondary winding of *T1501* to the output, and current will flow as shown by wave forms *B* and *D*. During a nonconducting half-cycle, these transistors present a high-impedance path. The resulting output current, wave form *E*, is full-wave rectified d-c and reverses polarity as the signal changes phase with respect to the reference voltages.

Fig. 7 shows the transistor servo amplifier along with the adapter plate used for substituting the amplifier in the computing system. The transistor amplifier and phase detector are on the printed circuit board in the foreground. The magnetic amplifier and its rectifiers are in the rear. Table I physically compares this transistorized unit with its vacuum-tube equivalent. The power required by this transistorized servo amplifier is 0.3 watt as compared to 6.9 watts for its vacuum-tube equivalent.

The performance of the transistor servo amplifier was evaluated while operating in a positional servo system composed of amplifier, servomotor, feedback potentiometer, and summing resistors. A positional servo of this type is used in the computing system to perform multiplication.

The frequency response of this system is shown in Fig. 8 and is seen to be comparable to that obtained with a vacuum-tube amplifier. Both amplifiers showed a static accuracy of approximately ±0.5 degree.

Fig. 9 shows the effect of ambient temperature and humidity on amplifier gain. The gain of the transistor unit is seen to increase with ambient temperature. This change, however, occurs in the magnetic amplifier, and the gain of the transistor amplifier and phase detector are essentially constant.

The substitution of transistors having current gains in the range of 30 to 60 had only a slight effect on amplifier gain. The substitution of transistors in the phase detector had no effect on its operation.

Conclusion

The use of transistor amplifiers in flight simulators as considered herein is both feasible and, from several points of view advantageous. The performance of such transistor amplifiers meets all necessary requirements and is generally equal to that of vacuum-tube equivalents. Furthermore, the transistor amplifiers offer advantages from their substantially lower power requirements, reduced size and weight, and anticipated improvement in reliability. The principal limiting feature of transistor amplifiers is their greater sensitivity to ambient-temperature changes. Although satisfactory operation was obtained over the required temperature range, the performance of the summing amplifier was marginal at temperature extremes. Future improvements, however, in both transistor design and circuit techniques will undoubtedly extend the range of amplifier application.

Development of Transcontinental Communications in Canada

J. W. NOYES
NONMEMBER AIEE

G. GAUDET
MEMBER AIEE

S. BONNEVILLE
NONMEMBER AIEE

THERE are three major communication agencies in Canada. The Trans-Canada Telephone System furnishes long-distance telephone service to the public across Canada and also provides privately leased telephone and telegraph circuits. The Canadian Pacific Railway Company and the Canadian National Railways each furnish commercial telegraph service throughout Canada, and they also provide a number of privately leased circuits, both telephone and telegraph.

This paper deals with the experience of the Trans-Canada Telephone System in developing a transcontinental telephone network. In pioneering a development of this nature and extent many novel problems were encountered. In addition to the usual design problems, there were others associated with the organization, administration, and operation of an entirely new system across difficult territory. The latter were the hardest to resolve since there had not been any previous experiences of a similar nature from which to benefit, whereas detailed engineering information pertaining to the design of toll plant is obtainable from a number of sources. In view of this it is proposed to discuss mainly the operational problems with only general information on the purely technical aspects.

Geography and Climate

In order to appreciate the difficulties which were encountered in welding this together, some knowledge of conditions in the country being crossed is required.

Canada's enormous area (3,846,000 square miles) makes it the third largest country in the world, exceeded only by Russia and China. It extends from the Atlantic Ocean on the east to the Pacific Ocean on the west; from the Arctic on the north to the United States on the south. While it is a giant geographically, most of the population is within 200 miles of the southern border.

The land consists of the following five geographical areas, as shown in Fig. 1:

1. The Maritime section in the east is part of the Appalachian Region and is in effect an extension of the New England coastal states. It is an area of mountain ranges which have been worn down through the ages. Fishing, agriculture, mining, and lumbering are the main occupations.

2. West of the Maritime Provinces and approximately in the middle of the country is the Laurentian Plateau, a huge U-shaped area of rock, lakes, rivers, forest, and swamp which covers some 45 per cent of the total territory of Canada. It is rich in mineral and forest resources but, with the exception of a few areas, it is not suitable for agricultural purposes. This part of the country is very sparsely populated, even in the south.

3. Further west are the St. Lawrence Lowlands which cover the southern parts of Quebec and Ontario. This is an area of gently sloping fertile plains, comprising about 50,000 square miles. It is the industrial heart of Canada and contains from one half to two thirds of the population of the country.

4. In the middle west is the Great Central Plain, an extension of the midwestern plains of the United States. While this is essentially an agricultural area (grain and livestock), large oil and gas deposits are being discovered.

5. In the extreme west is the Cordilleran or Pacific Coast region, an area, about 400 miles wide, of high mountains, the Rockies, interspersed with valleys. Farming, fruit growing, mining, lumbering, and fishing are the basic industries of this region.

From this description it is obvious that Canada has a difficult topography. Continuous settlement across the country is not possible as the most desirable sec-

J. W. NOYES, G. GAUDET, and S. BONNEVILLE are with Bell Telephone Company of Canada, Ltd., Montreal, Que., Canada.

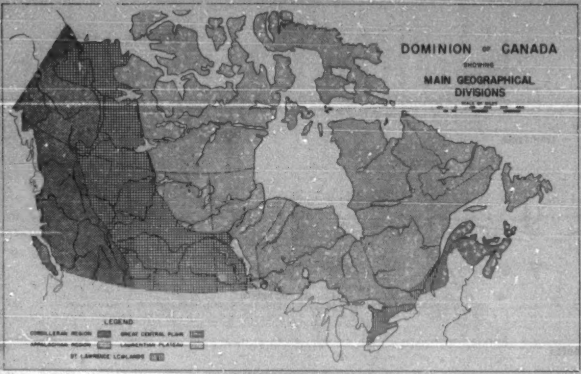

Fig. 1. Main geographical divisions

tions from the point of view of climate and fertility are separated from each other by large areas that can support only a very thin population. This situation is illustrated in Fig. 2 which shows the distribution of population. Two barriers which will be noted particularly are the thinly populated section in the middle of the country and the Rocky Mountain region in the west.

The climatical conditions across the country are difficult also. Hot summers and cold winters give rise to a wide range in temperature, from 60 degrees Fahrenheit below zero to 100 degrees above. Hoarfrost, sleet, and heavy snow are other conditions that have to be considered. The handicaps of topography, geography, climate, great distances, and natural barriers separating populated areas, have posed serious problems in the design, construction, and operation of a transcontinental telephone service.

Background of the System

Telephone service in Canada is provided by seven major telephone systems and together they span the Canadian mainland. Each of them operates an extensive telephone network within its own territory. However, prior to 1928 these systems were fairly well isolated from each other as there were very few intersystem telephone circuits. Most of the long-distance calls between adjacent systems were routed through the United States.

The question of a telephone system across Canada was first studied in 1922. It was considered then that the difficulties in providing a telephone line across the Rocky Mountains, the 1,000-mile stretch of forests, lakes, and swamp from Winnipeg to Sudbury, and the 400 miles of sparsely settled country between the St. Lawrence River and the Maritimes were insurmountable. The matter was not pursued further until 1929 when it was restudied in the light of later technical developments and an expanding economy. The results of this study were favorable, and it was decided to proceed with the construction of a transcontinental telephone system across Canada. To this end the seven major telephone systems serving the country formed the Trans-Canada Telephone System with each one of them providing the facilities needed in its own territory.

An Engineering Committee was formed to co-ordinate the over-all design and construction of the system. It is made up of a representative from each of the member companies, usually the chief engineer. This group is responsible for the development of plans for the construction of additional facilities to meet the forecast for circuit requirements, toll switching plans, and transmission design on both a current and long-range basis. Until recently it was responsible also for traffic forecasts, estimates of circuit requirements, plant maintenance, traffic routing, and other matters.

The route followed across the continent is shown in Fig. 3. It extends from Halifax on east coast to Vancouver on the west, passing through the key cities of St. John, Montreal, Toronto, Fort William, Winnipeg, Regina, and Calgary. The over-all distance is about 4,200 miles.

Each of the nine points is served by long-haul toll circuits which connect it with a number of the other key cities. These circuits constitute the backbone of the Canadian continental telephone network. Each of these offices is a main switching center, and serves as the point of connection with the telephone network in the territory which it serves. For example, all toll traffic with points in the Province of Manitoba and the outside world, is routed through Winnipeg. Similarly, practically all traffic with points in the Province of Saskatchewan is routed via Regina. Exceptions to this arrangement are a few of the other larger toll centers, which have direct circuits to one or more main switching centers in addition to their own home office. The figures show the number of long-haul circuits that were available in 1932 when the

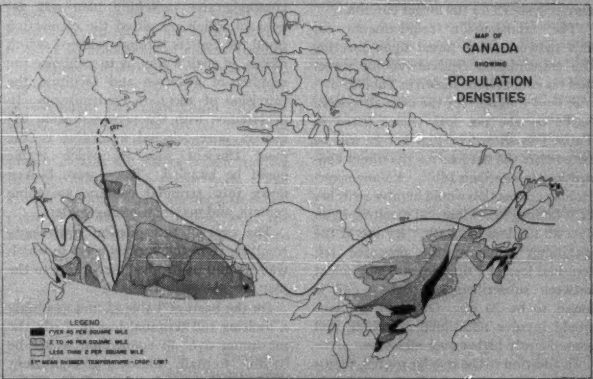

Fig. 2. Population densities

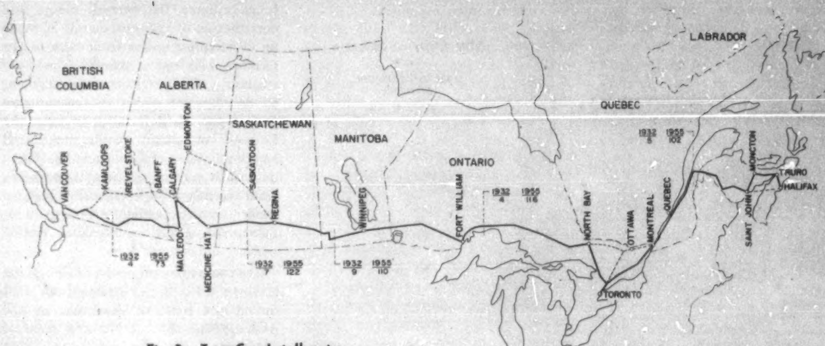

Fig. 3. Trans-Canada toll routes

system was inaugurated and the number that will be available on completion of the current construction program.

Early Design: Open-Wire and C Carrier

The route was developed initially for open-wire and *C* carrier operation. It was designed throughout most of the distance for an ultimate of eight pairs of wire with superimposed *C* carrier systems for long-haul circuits, in addition to the intermediate and short-haul circuits.

TRANSMISSION CONSIDERATIONS

Transmission design requirements in respect to "transmission equivalent," noise, crosstalk, and distortion for both direct and switched connections indicated the desirability of restricting the length of the voice-frequency circuits and using carrier systems for the longer circuits.

The transmission requirements for this network were based upon meeting the transmission equivalents for direct and via connections shown in Table I.

A level diagram for the over-all system based on the net loss values listed in Table I is shown in Fig. 4. It will be noted that the net loss for the direct connections is 9 decibels (db). A Vancouver-Halifax connection would involve switches at Winnipeg and Montreal resulting in an over-all net loss of 15 db. By use of the maximum value of the proposed toll terminal loss of 7 db, the total equivalent between subscribers on such a call is found to be 29 db. Other connections would involve additional switching and consequently higher over-all losses.

In addition to the regular routes, shown for the Trans-Canada System, certain alternate routes shown in Fig. 5 were authorized for service protection. It will be noted that they were provided through connections via United States' points.

At that time two methods were used to introduce gain at switching points, namely, by means of cord circuit repeaters and pad switching. Cord circuit repeaters required the provision of a suitable balanced switching circuit to permit the via circuit to be switched through the repeaters. In addition, suitable switchboard positions were required which involved a 2-jack multiple.

The terminal repeater switching pad plan was just being introduced. This plan provided for the removal of transmission loss at toll switching points by automatic control of artificial lines. This pad plan was used at centers equipped with no. 3 toll switchboards and the cord circuit repeaters were used at others.

As traffic and facilities expanded, a comprehensive switching plan was developed which permitted the connection of all toll centers through selected switch offices, in such a way as to minimize the number of switches and facilitate the provision of adequate transmission. In accordance with the proposed plan, toll centers were selected according to the most efficient way in which traffic could be handled. These were broken down into terminal centers, switching centers, and major switching centers.

The over-all transmission equivalents resulting from the various ways in which traffic could be handled, according to the plan, are shown in Table II.

On the basis of Table II and assuming a limiting toll terminal loss of 7 db, the maximum over-all connection would be 31 db. Actually, the over-all equivalent would vary somewhat from Table II depending upon the minimum working net losses obtainable from the various links. This item was important at that time as open-wire facilities which are subject to weather conditions comprised the majority of the construction.

Because of minimum via net loss considerations it was necessary to use 4-wire circuits equipped with echo suppressors or carrier telephone systems for facilities longer than 1,200 miles. The design of the system covered in general the use of 165-mil copper wire with superposed *C* carrier. With this arrangement it is possible to meet the maximum working net loss limit as suggested. As the system consisted mainly of open wire it was extremely important that the maintenance of the circuits be excellent in order to avoid variations greater than contemplated in setting up the design data. If these variations were exceeded, very serious impairment to transmission would result. Other factors considered at the time were noise, crosstalk, and distortion. The measurement of noise was made on a comparison basis and was expressed in noise units. The noise objective was 200 noise units at the −9-

db level. Crosstalk at that time was measured in crosstalk units and the objective was 1,000 units for carrier and toll cable circuits at the −9-db level point, and 1,500 units for open-wire voice circuits.

Although distortion is a factor, it was not practicable to specify distortion limits except that the design of the component parts of the circuit should be such that distortion impairment was not intolerable. It is of interest to note that at the time it was considered desirable to limit the number of carrier systems operated in tandem to two because of cumulative distortion effects. This resulted in the use of a mixture of voice-frequency open-wire and carrier facilities for long telephone circuits. With present-day knowledge and techniques, such restrictions would not apply.

Where carrier was involved, line filters with a cutoff frequency of 5,000 cycles were used so that the circuits would be available for the transmission of programs.

It was recognized that phantom circuits would have to be abandoned in order to meet crosstalk limits on a transcontinental basis. Although it was known that the limit of 1,500 crosstalk units was somewhat higher than would normally be tolerated, it was felt that it would be a lower limit; in fact it was indicated that in some combinations of closely coupled circuits, somewhat higher values might be experienced. At that time, therefore, development in transmission arrangements envisioned the use of long-haul carrier systems, which eliminated the phantoms and the use of 8-inch spacing between wires of the carrier pairs. The spacing between pairs was increased also from 12 to 16 inches which, with the closer spacing of the wires, operated to reduce the crosstalk effect considerably. The decreased spacing between the wires of a pair also tended appreciably to reduce those components of noise arising from voltage which are directly induced between the wires of telephone circuits by extraneous sources.

New transposition layouts were designed to provide satisfactory noise and crosstalk performance on systems of this length. One of these, an 8-span layout known as the *K8* system, was provided for new construction. A second type of system, based on a 10-span layout known as the *K10* system, was applicable to existing leads on a unit basis without major changes in the existing transposition design.

These transposition systems were being developed while the work was in progress. There was no previous experience with the operation of carrier systems of the length planned for the Canadian network. As a result, a very conservative approach was exercised in the application of the transposition design. Transposition poles were located as precisely as field conditions would permit. This resulted in considerable expenditures which later conditions showed were not necessary.

To obtain suitable transmission results it was necessary to provide the best available grade of outside plant facilities consisting of 165- or 128-mil copper wire on *CS* insulators at 8-inch spacing. The use of these sizes of wire on *CS* insulators has the advantage of lower attenuation and of greater stability compared to the use of smaller gauge wire on ordinary toll insulators. With the larger gauge wire the fluctuations of equivalent are less with temperature and humidity changes. The improved glass insulators, moreover, effected a marked reduction in attenuation and in the variation of attenuation with weather conditions. Eight-inch-spaced nonphantomed facilities were required to meet the crosstalk design limits for circuits of the type and length involved in the Trans-Canada System.

The repeater points were spaced to take advantage of the large-gauge wire

with the improved glass insulators at 8-inch spacing. In establishing the repeater, spacing allowance was made for sleet, hoarfrost, and wet snow conditions. On a call from Halifax to Vancouver, 22 intermediate repeater points were involved. The average repeater section was 180 miles in length with the longest at 250 miles.

Other factors introduced to improve transmission were the use of transposition break irons to provide point-type transpositions. In addition an improved glass insulator mounted on steel pins, bonded together electrically, was developed to improve insulation conditions on the open-wire lines. These were known as *CS* insulators. Subsequent experience showed that the advantages of the bonding were not significant.

Because the Trans-Canada facilities were superimposed on an existing structure, a problem arose in co-ordinating the new requirements of the long-haul circuits with those in existence. In certain cases the repeater points on the two systems did not coincide. The co-ordination of transmission levels was a complex problem and was complicated further by the need for providing emergency carrier assignments over existing 114-mil copper pairs between Sudbury and Winnipeg and 104-mil pairs in other sections.

OUTSIDE PLANT

When the transcontinental toll route was being developed, as much use as possible was made of existing toll leads in the territories of the member systems. To meet the strength requirements of a class *A* line, however, it was necessary to rebuild completely some 2,000 miles of line, equivalent to about half the length of the route, and to add poles in other sections. Where this was done the new poles were spaced on an average 130-foot span basis. In the thinly populated, 1,000-mile section north of Lake Superior, between Sudbury and Winnipeg and through the Rocky Mountains in the west, arrangements were made to carry the telephone circuits on the Canadian Pacific Railway pole lines. This avoided the need for duplicate lines in these difficult sections.

In keeping with the ultimate view of requirements, the top gain, or two top gains, as the case may be, were reserved for the long-haul circuits. As the existing 104- and 114-mil wire on these cross-arms was not considered to be suitable for the backbone circuits from the point of view of strength and transmission characteristics, it was removed and relocated on lower arms. The space thus made available was used for new heavy-gauge wire.

The largest size of standard copper wire for telephone purposes, 165 mil (1/6 inch in diameter), was erected initially over three quarters of the route, with 128-mil copper wire used throughout the balance of the distance. One of the principal reasons for using 165-mil wire was for strength. It was thought that it would withstand the weight of wet snow, sleet, and other mechanical strains better than would the 128-mil wire. Subsequent experience did not support this premise as the incidence of wire breaks on 165- and 128-mil wire did not show any significant difference. It view of this, 128-mil wire has been used in most sections for the construction of additional pairs except on the railway pole line north of Lake Superior where the heavier gauge wire continued to be used.

The entrance cables at the various repeater stations and terminal offices were generally the composite type, with 13-, 16-, and 19-gauge complements, either quadded or paired and loaded as required. Separate east and west entrance cables were installed at each point. The conductors to be used for *C* carrier operation were segregated and loaded for this purpose. Normal protection was provided at the various stations and at the cable and open-wire junctions. Special protection was provided as needed.

Growth

The growth in long-haul circuit mileage is shown in Fig. 6. It will be noted that when transcontinental telephone service across Canada was inaugurated in 1932 there was a total of only 20,000 miles on long-haul circuits provided to handle the traffic. As a result of the depression, these facilities were sufficient to handle the traffic until 1937 when the country began to emerge from the economic morass. Then, the war years brought an ever-increasing demand for telephone service, as indicated by the growth in circuit mileage which was limited by shortages of material and equipment. This growth has accelerated in the post-war years and now there is a total of just under 400,000 miles of long-haul circuits carried across Canada on open-wire lines.

By 1947 the rapid growth in circuits needed to handle the traffic began to exhaust the *C* carrier capacity of the open-wire line. About 30,000 miles of long *C* systems, or 90,000 channel-miles, were in operation across the country, of which almost 60 per cent were made up of systems 1,000 miles or more in length. Some typical systems are Toronto-Calgary, 2,170 miles; Montreal-Winnipeg, 1,400 miles; Toronto-Winnipeg, 1,250 miles; and Regina-Vancouver, 1,130 miles.

The next step in the race with the rapidly expanding demand for telephone service across the continent was develop the open-wire line for *J* carrier operation. The first *J* system was placed in service between Toronto and Winnipeg in 1948. The growth in the development of broad-band open-wire carrier systems across the country has been rapid. There are now over 16,000 miles of *J* systems in service providing a total of about 200,000 circuit-miles, or about half of the total long-haul circuit mileage across the country. Systems over 1,000 miles in length include Toronto-Winnipeg, 1,250 miles; Montreal-Winnipeg, 1,400 miles; and Winnipeg-Vancouver, 1,700 miles. The *J* systems have been used for the longer circuits with some of the *C* systems cut up to provide circuits between adjacent switching centers, e.g., Calgary-Regina and Regina-Winnipeg circuits.

J Carrier Developments

By about 1945, toll circuit relief in the Ontario and Quebec portions of the Trans-Canada System was being provided by means of a rapidly expanding toll cable backbone route extending from

Toronto to Quebec via Kingston, Ottawa, and Montreal, a distance of over 500 miles, with a network of cable branches reaching most of the important traffic centers in the territory. Voice-frequency loaded cable facilities and short-haul carrier systems were assigned to relatively short distance circuits, while *K* carrier facilities were assigned to the longer circuits in the backbone route.

For the remaining, and by far the longer, portion of the Trans-Canada route west of Toronto and east of Quebec, engineering studies indicated unmistakably that an extended use of existing open-wire facilities by means of *J* carrier offered the most practical means of relief for the time being. This plan, however, presented some unusual technical difficulties which will be discussed in the following.

Introduction of *J* carrier operation made it necessary to carry out extensive changes and rearrangements to the open-wire lead to make it suitable for this type of operation. This included retransposition, the making of gaps of at least 80 feet in the open-wire line at each repeater station, installation of new entrance cables and rearrangement of existing cables, installation of suitable crosstalk suppression and protective devices on each pair of wires at the terminal poles, construction of new auxiliary repeater buildings, etc.

The most critical bottleneck was between Toronto and Winnipeg, 1,250 miles, largely because of the section Sudbury-Winnipeg, 978 miles, where the Trans-Canada facilities consisted basically of four pairs of 165-mil copper wire on the top arm having an 8-inch–16-inch–8-inch configuration, with *K10* transpositions and full *C* carrier development. These 165-mil top arm pairs were in the somewhat disturbing company (from a transmission co-ordination standpoint) of non-co-ordinating Railway Company 114-mil pairs on lower arms and frogged steel and copper-pole pairs of wires on the two top arms. To increase the complexity of the problem, in many sections the lowest Railway Company crossarm carried "untouchable" block signal wires which were outside the authority of the Railway Company's Communication Department. It was anticipated that these wires might act as tertiary paths which could contribute to run-around crosstalk or singing.

Because this Toronto-Winnipeg section was the first section in the Trans-Canada route where *J* carrier was developed, and because it also presented some of the most challenging problems, the treatment chosen will be described as typical of problems met in subsequent *J* carrier developments west of Winnipeg and east of Quebec.

Since *K* carrier facilities were already available from Toronto to Oshawa, an obvious solution was that *J* systems west of Oshawa should be extended to Toronto by *J-K* conversion at Oshawa. The *J* carrier design problem was now restricted chiefly to the Canadian Pacific pole-line section in the rugged country between Sudbury and Winnipeg.

J REPEATER SPACINGS

In the layout design of a *J* carrier system of more than 1,000 miles in length, the choice of repeater spacings (and thereby the determination of the number of repeater stations) has a major influence on the cost of the project and on the expected performance.

It is an inherent weakness of open-wire carrier systems that they cannot be built economically for complete immunity to service interruptions under extreme weather conditions. A compromise has to be made at some point where greater insurance against service interruptions would necessitate disproportionate increases in costs. In this project, it was decided to use a design aimed at limiting system outages to not more than 5 to 10 days per year.

A program of high-frequency transmission-line loss measurements was undertaken for several strategically chosen sections between Oshawa and Winnipeg to indicate the range of line-loss variations that could be expected in different regions along the route and over the winter months. Inquiries were also made of meteorological bureaus, farmers, and railway and telephone craftsmen, as to their records or recollections of sleet, freezing rain, hoarfrost, or wet snow incidence in different line sections. Information from such sources provided a surprising amount of contradiction but was of some assistance.

The exact choice of repeater station locations was influenced by many factors. It was important that each station be close to an existing railway station or siding and that it be at or near a neutral point in transposition layout (*S* point) to minimize the need for retransposing. Terrain had to be considered. For instance, marshy ground or steep slopes were not acceptable. Availability of power supply was another factor.

After all the afore-mentioned aspects had been duly considered, a *J* repeater layout was designed with spacing ranging from 35 to 70 miles, and transmission capability of overcoming open-wire losses under ice conditions of more than 2.0 db per mile in the sections considered most exposed to ice incidence down to as little as 1.1 db per mile in sections estimated as relatively immune.

ELECTRICAL CO-ORDINATION

The initial project of *J* development in the bottleneck, Sudbury-Winnipeg, involved only one system in the first stage, to be followed by a second system some 2 years later, and with an ultimate design of eight or possibly nine systems.

Attenuation-frequency measurements showed that the existing top arm with *K10* transpositions had two pairs on pins 1–2 and 7–8, free from attenuation peaks and suitable for *J* carrier. Of course, the design of the first system involved no *J* crosstalk problem, but it did present unusual repeater singing problems which, without proper remedial measures, would have reduced the usuable maximum repeater gains of 77 db by an intolerable margin of 15 db or more.

At auxiliary repeater stations, standard suppression measures were estimated to be adequate, and this was confirmed by later experience. The railway signal wires on bottom crossarms were a cause of worry but actually gave little trouble.

The chief difficulties were found at some of the main repeater stations, which already served as *C* carrier and voice-frequency repeater points, where loaded entrance cables were unusually short and did not provide the degree of *J* carrier frequency crosstalk and singing suppression (via tertiary paths) as is normally assumed for main repeater stations. In one case, the problem was complicated by the adjacency on both sides of the repeater station of another railway pole line which acted as a tertiary path.

These abnormal situations were controlled by unusual application of filtering arrangements normally reserved for auxiliary stations. These in turn necessitated special bay layout arrangements, and in one case building modifications to increase ceiling height beyond what would normally have been required.

CONSTRUCTION PROBLEMS

Most of the proposed auxiliary *J* repeater stations were to be in wild bush country, accessible only by railroad. Arrangements were made with the Railway Company to build sidings where necessary, to provide suitable railroad cars for the living accommodation of the installing crews, and to serve as storage sheds for equipment. Portable oil heaters and gasoline-driven electric generators for

Fig. 7 (above). Auxiliary J repeater building

Fig. 8 (right). Bunkhouse

lighting and for auxiliary electric service supplies (such as soldering irons, etc.) had to be provided. In several cases, automatic gasoline power plants had to be installed and suitable arrangements had to be made for gasoline storage which conformed to local regulations. Ventilation, for summer and winter, of unattended auxiliary repeater stations with automatic power plants presented many problems; for instance, poisonous exhaust gases from the gasoline engines being sucked back into the engine room by the automatic intake fans. There was also a danger of the exhaust pipe of the engines which projected outside of the building becoming choked by snow drifts or icicles, thereby incapacitating the engines. However, these problems, as well as many minor ones, were finally solved.

TRANSMISSION DESIGN FOR THE SECOND AND ADDITIONAL J SYSTEMS

A second *J* system could have been installed on pins 7–8 between Sudbury and Winnipeg while the first system was operating on pins 1–2 without changing the existing *K10* transpositions. With a view to the future, it was realized that the next step would involve retransposition to some suitable *J* design and that execution of this plan would result in many interruptions or impairments of service while the retransposition was underway. It was therefore decided to retranspose the top arm to the *J5* design before the second *J* system was installed.

At this stage, the problem of crosstalk between *J* systems arose. Because of the great length of the systems, and of the many adverse conditions involved, it was decided to take other measures to insure control of crosstalk beyond retransposing the top arm. These measures included the following:

1. Respacing of pins on top crossarm from the 8–16–8-inch configuration to 8–24–8-inch configuration. Six-inch wire spacing was considered unsuitable because of the liability of wire contacts under prevailing weather conditions. The respacing from 8–16–8- to 8–24–8-inch configuration involved a question as to whether old crossarms, originally bored for 12–12–12-inch configuration, then rebored for 8–16–8-inch spacing, and now to be re-rebored on 8–24–8-inch basis, could take the reboring without dangerous weakening. Studies and tests led to the conclusion that if the crossarms were free from decay, the reboring should cause no weakening as the critical breaking point was close to the pole and was not affected by reboring along the arm.
2. Removal of pole pairs on two top arms. This was predicated by step 1, due to space considerations, and because in any case the *J5* transposition does not provide for pole pairs.

FINAL TRANSMISSION DESIGN

With repeater singing and run-around crosstalk assumed to be under control, there remained two outstanding problems: noise and echoes.

These challenges were met by the use of compandors on critical channels, and by the judicious application of echo suppressors.

UNUSUAL PROTECTION PROBLEMS

The western portion of the Trans-Canada route is laid out roughly along the 50 degree parallel of North latitude. This geographical situation, in combination with the prevalent ground conductivity, may account for the severe electrical disturbances on line wires which have been experienced, particularly between Sudbury and Winnipeg, as a result of magnetic storms. Sporadic periods of rapidly fluctuating voltages between line wires and ground with peaks of between 500 to 1,000 volts have been experienced year after year. In these magnetic storm periods, carbon protectors broke down and some remained permanently grounded which resulted in circuit unbalances or short circuits. For stations in bush country with access difficulties, these protector troubles often resulted in seriously long service interruptions.

To remedy this situation, drainage coils were installed in association with carbon protectors, connected in such a way that permanent grounding of a pair of carbon blocks would affect only direct currents and would leave all carrier frequency currents relatively unaffected. Installations of 1,000-volt protectors were also made at strategic points to minimize chances of service interruptions due to troubles at points not readily accessible.

OUTSIDE PLANT PROBLEMS

At main repeater stations where long entrance cable facilities were already in place, pole-mounted *J* line filter installations were provided to separate the *J* carrier frequency currents and transmit them over nonloaded paper-insulated entrance cable pairs. Unfortunately, unlike so-called "junction filters" which separate all carrier from voice frequencies, these *J* line filters are sensitive to low temperatures and are liable to be permanently damaged if exposed to temperatures below freezing. Special pole-mounted filter boxes were therefore designed with thermostatic control of electric heating units and automatic alarms in the near toll office when temperature in the filter box dropped to near-danger point. Provision was also made at each box to supply emergency power for the heaters from the repeater station 130-volt battery in the event of commercial power failure.

Vol.
Pt. 1
1956

Entrance cables at the various stations were generally underground. In these locations where the entrances were in muskeg or low lying land and where drainage was impracticable, paper-insulated lead-covered cables were placed in transite ducts, not encased, and the spiral four cables were placed inside $1^{1}/_{2}$-inch-diameter steel pipe. When the pipe joints were properly made and the pole end was adequately sealed, no trouble has been experienced. However, where the joints or seals were not properly made, water entered the pipes and during the winter caused spiral four cable failures due to crushing by ice in the pipe.

Span-type transposition brackets were used in connection with the retransposing to avoid extensive pole respacing, although there had been very little actual experience with this type of bracket at the time. The brackets were made of magnesium initially to keep their weight down to a minimum. This did not prove to be satisfactory, however, because of frequent failures due to fatigue. To overcome this, aluminum has been used for new brackets with excellent results. Later experience has raised doubt as to the efficiency of span brackets in reducing crosstalk under some conditions.

J Carrier Development West of Winnipeg and East of Quebec

The foregoing outline of the engineering design of the *J* carrier systems between Toronto and Winnipeg covers all the major problems that had to be met on other Trans-Canada *J* carrier developments. The prairies presented problems of access to stations and of the possibility of heavy hoarfrost in several sections and frequent gale force winds in other sections, as well as an extreme range of temperatures. In Alberta temperatures sometimes vary by 50 degrees in less than 1 hour when the Chinooks blow in from the Rocky Mountains.

The *J* carrier development in British Columbia naturally presented a severe engineering problem because of the extremely mountainous nature of the country, the wide weather variations, and the snow and rock slides. In the section in between Hope and Princeton, the Trans-Canada wires were on a railway pole line traversing a valley where snow slides had several times carried away miles of pole line and had buried railway tracks. To protect the *J* carrier systems against this possibility, a new pole line was built along a safer route. This line was provided initially with three pairs of 8-inch-spaced 128-mil copperweld wire, *J5* transposed.

Arrangements with Railway Company

As indicated earlier, the 1,000-mile, thinly populated section north of Lake Superior was a serious obstacle to the development of a transcontinental telephone service across Canada. Construction of a pole line across this barrier was out of the question at the time. The cost would have been prohibitive, maintenance would have been very expensive, and the volume of business to be handled was relatively light. Indications were that it would be many years before the volume of traffic could carry the cost of an open-wire telephone line.

The Canadian Pacific Railway had a pole line in this section which was built in conjunction with the railway line. It was used for telegraph business and for railway operations. By arranging with the Railway Company to carry the telephone circuits on its pole line, it was possible to bridge this gap.

The basic agreement with the Railway Company covers the construction of four pairs of wires on the top crossarm over a distance of 1,000 miles for telephone purposes, including entrance cable facilities. They were constructed to the Telephone Company's specifications and leased to them exclusively for an initial period of 20 years which has subsequently been extended. The Telephone Company was given the right to operate at any frequency above 100 cycles per second over them, and the railway used the band under 100 cycles for d-c telegraph service. The operation of any form of commercial telegraph over these facilities by the Telephone Company was expressly forbidden.

The cost of rearrangements to the railway plant on the line to provide space for the new pairs and the cost of retransposing existing railway facilities to coordinate with those constructed for the use of the Telephone Company was borne by the latter.

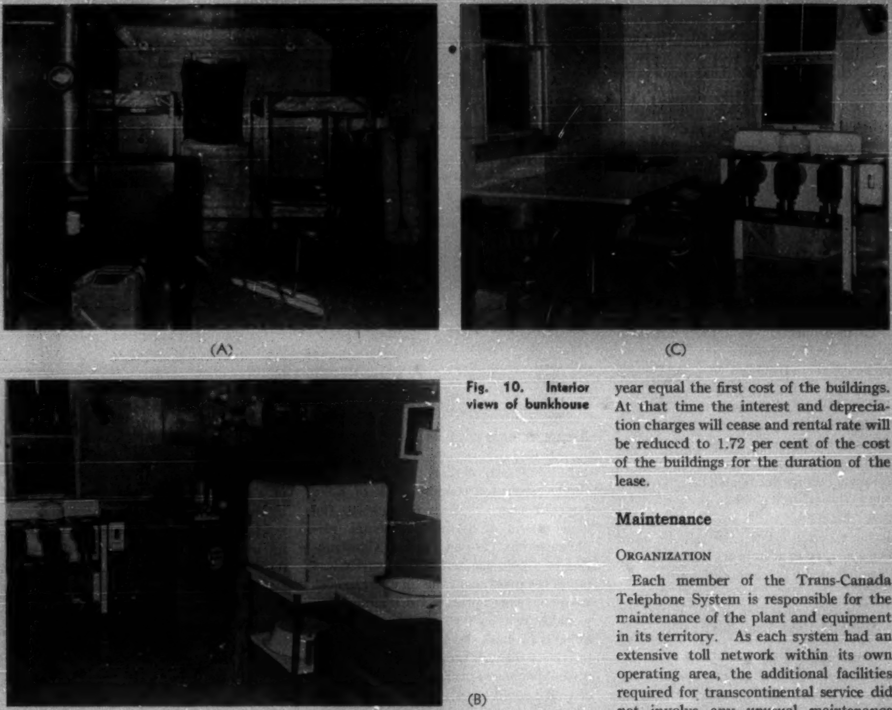
The Telephone Company provided its own *C* carrier and voice-frequency repeaters, test equipment, etc. It was located in space made available in the Railway Company's existing repeater offices on the route. The Railway Company maintained the telephone equipment in its offices and also furnished power.

With the introduction of *J* carrier on the lead by the Telephone Company, it was necessary to make extensive changes and rearrangements to the pole line to make it suitable for this type of operation. The Railway Company carried out all the rearrangements and changes and built the new buildings to the specifications and plans furnished by the Telephone Company. The Telephone Company reimbursed the Railway Company for the cost of the retransposition, the changes, and the rearrangements, and leased the new buildings.

Rental Rates

Open Wire

An interesting feature of the arrangements with the Railway Company is the formula developed to determine the rental rates for the pairs of wires leased to the Telephone Company. These pairs were constructed at different times, and the formula was designed to reflect any variations which might occur in the price of copper during this period. It served to protect each of the contracting parties as the rental charge for a new pair of wires could be determined within close limits before the work was authorized.



(A) (C) (B)

Fig. 10. Interior views of bunkhouse

The general formula is as follows:

$\$28.43+(1.072\times N)$ where N is the cost of copper wire in cents per pound

The formula is based on costs which prevailed before World War II and a route mileage of 973 miles.

In the case of the first pair of wires provided for the use of the Telephone Company, the rental rate derived by means of the formula was increased by a fixed amount per circuit-mile per year. This amount covers the charges for floor space reserved for the Telephone Company's equipment in the four Railway Company main repeater stations; house service, insurance and taxes on this space, replacement of crossarms, entrance cables, and cable loading. At such time as the lease for the pair carrying this charge expires, the amount is then added to the rental for one of the other pairs.

Auxiliary J Repeater Buildings

As indicated previously, the Railway Company constructed the new buildings required at the auxiliary *J* repeater sites and leased them to the Telephone Company. The buildings are located on the railway right-of-way at locations selected by Telephone Company engineers. The heating and ventilating equipment, power plants, fuel oil storage, and gasoline storage where required, as well as all the carrier equipment and associated apparatus at the auxiliary repeater stations, was provided by the Telephone Company.

The rental for these buildings is based on the exact cost of the buildings and includes the following items:

	Per Cent Per Year
Interest	5.0
Depreciation	3.27
Administration	0.5
Maintenance	0.5
Taxes	0.37
Insurance	0.10
Use of right-of-way	0.25
Total	9.99

This rate is to be used for determining the rental charges until the amortization charges accumulated at 5.0 per cent per year equal the first cost of the buildings. At that time the interest and depreciation charges will cease and rental rate will be reduced to 1.72 per cent of the cost of the buildings for the duration of the lease.

Maintenance

ORGANIZATION

Each member of the Trans-Canada Telephone System is responsible for the maintenance of the plant and equipment in its territory. As each system had an extensive toll network within its own operating area, the additional facilities required for transcontinental service did not involve any unusual maintenance difficulties. The main problem was that of training the plant forces in the special problems associated with the introduction of new instrumentalities, techniques, and operating procedures.

The most difficult maintenance problem concerned the facilities carried over the railway pole line north of Lake Superior. During the early years when the facilities consisted of open-wire and *C* carrier, all the repeaters were located in the Railway Company offices. These offices were staffed by railway employees trained to maintain and operate the communication facilities of the railway. Arrangements were made to have this staff maintain the telephone equipment also. To this end the men were trained in Bell System techniques and methods, and furnished with the necessary test gear and practices. Their salaries were prorated between the Railway Company and the Telephone Company in proportion to the work performed for each company. This is determined by periodic studies involving an inventory of the equipment owned by each company in each of the main repeater offices and an estimate of the man-hours required for both equipment and service maintenance on each company's equipment using work units derived from Bell System experience.

Introduction of *J* carrier operation across the continent gave rise to new maintenance problems, such as the maintenance of terminal and repeater equipment at locations where a regular maintenance staff is located. The problems here are quite similar to those encountered in maintaining other types of toll equipment. Time spent on routine maintenance of the *J* equipment in the attended stations is not excessive, amounting to about 6 hours per quarter per terminal and 3 hours for each repeater.

Periodic interchange of located personnel with those assigned to the maintenance of auxiliary stations on a despatch basis is desirable. This scheme results in periods of greater supervision and training. It also permits greater flexibility in the use of available staff.

Servicing of the auxiliary *J* repeater stations is done on a motorized despatch basis except in the undeveloped section north of Lake Superior. In a reasonably well developed territory, regular toll offices are distributed so as to permit the despatch of personnel from these offices to the adjacent auxiliary stations.

Routine maintenance requires that each auxiliary station be visited every quarter. While the number of working systems in a station governs to some extent the maintenance effort required, experience shows that these visits consume about 50 hours per station per quarter. Travel time is in addition to this and varies according to the distance that must be travelled. Visits in connection with trouble alarm indications have been averaging about one per auxiliary station per month. Time taken on these visits varies with the nature of the trouble with travel time, of course, in addition.

Maintenance of the unattended *J* repeater stations in the undeveloped section along the railway line north of Lake Superior presented a difficult problem. Most of these stations are not accessible by road and can only be reached by train, usually freight.

Two plans for maintaining these offices were studied. One was to use Telephone Company personnel, and the other was to have the Railway Company do the work. The latter plan was adopted as the most satisfactory solution. Arrangements were made to have three railway telegraph men assigned full time to take care of the equipment at the auxiliary *J* repeater stations. The Railway Company is reimbursed for the wages and expenses of these men by the Telephone Company. Each man has four to five stations assigned specifically to him. He uses the main repeater station in his section as headquarters.

At nine of these stations accommodation for lodging and meals does not exist as they are miles from any habitation. Fig. 7 shows a repeater building with a bunkhouse. The dead-end pole on one side of the station can be seen also. The wires on the other pole are signal wires which the Railway Company would not allow to be carried in and out of the repeater station. As the train schedule does not permit a man to enter and leave one of these stations on the same day and still have adequate time for maintenance work, it was necessary to provide some form of living accommodation. The first approach to the problem was to provide a folding cot, blankets, electric hot plate, dishes, cutlery, and cooking utensils in the repeater station but this arrangement was far from satisfactory. Meals were prepared under difficulty with little space available for eating and storage of food or utensils. Sleeping among bays of clicking relays and whirring motors was not conducive to a good night's rest, and the depressing influence of battery fumes, absence of natural light, and cold floors added to the inhospitable living conditions.

The solution to this problem was the construction of wooden bunkhouses, 28 by 10 feet in size, adjacent to the auxiliary repeater station, see Fig. 8. The buildings are insulated and lined on the inside with plywood. Fig. 9 shows the floor plan and arrangement of the different items of equipment. Interior views of these cabins are shown in Figs. 10(A), (B), (C). It will be noted that the buildings are well furnished with an oil heater, oil stove for cooking, two double-deck bunks, a small electric refrigerator, table, chairs, kitchen utensils, and blankets, and that they are stocked with provisions.

The buildings were built by the Railway Company and are leased to the Telephone Company. The rental paid is based on a formula similar in principle to that used in determining the rental charges for the auxiliary repeater buildings.

A number of auxiliary repeater stations where commercial power was not available were equipped with gasoline-powered engine-driven generators. The maintenance of the engines was kept up by the Telephone Company and not the roving attendants. These stations were visited every 2 months in winter and 3 months in summer by two mechanics from the motor vehicles section who spent 3 days in each station checking the engines.

Table III. Plant Maintenance Results

Cross Section	First Six Months 1954	First Six Months 1955
Montreal and Toronto-Maritimes	5.52	5.74
Montreal and Toronto-Winnipeg	8.58	4.25
Winnipeg-Regina	9.47	7.48
Regina-Calgary	6.86	11.83
Calgary-Vancouver	15.95	10.84

Several years' experience with engine-operated power plants has resulted in a number of modifications to improve their over-all operation. Two of the most important changes are as follows:

1. The normal ventilating arrangement of the engine crankcase provides for feeding the exhaust oil fumes back into the intake manifold. The oil vapor forms carbon when it comes in contact with the hot intake valves. Accumulation of carbon caused the valves to stick and burn which necessitated a regrinding job every 3 months. To overcome this, each engine was modified to exhaust the fumes directly outdoors. This has reduced the frequency of the valve-grinding job.
2. The oil capacity of the engine crankcase is 5 quarts. The oil consumption required a visit to each station every 3 weeks to replenish the oil. The need for these frequent trips was overcome by installing a 5-gallon reserve oil supply tank which fed oil into the engine crankcase under control of a float valve.

It should be pointed out that power supplied by engine-operated power plants has proved to be a costly undertaking and should be avoided if it is at all possible to bring in commercial power.

RESULTS

The maintenance results experienced on this network follow the general pattern for open-wire plant. The principal sources of trouble have been due to sleet, hoarfrost, wet snow, protector operation due to voltage surges, broken insulator, swinging short circuits, train wrecks, highway accidents, etc. Particular mention should be made of snow slides and rock slides in the Rocky Mountain section which took the lead out for days at a time. This condition was improved by a reroute of the line in the worst section coincident with the *J* carrier installation. It is also interesting to note that interruptions due to hoarfrost or wet snow have mostly occurred during early morning hours, when traffic was light, and clearance generally happened soon after sunrise.

The over-all performance of the carrier systems has been excellent with no unusual maintenance and operational problems arising out of their extreme length. While several of the systems are approximately 1,000 miles in length, it was recognized that this was about the upper limit for satisfactory regulation. Consequently, the 1,700-mile Winnipeg-Vancouver *J* system now being installed will have its regulation broken at Calgary into two sections.

Recent plant maintenance results are listed in Table III. They show the lost time per 100 circuit-miles for the Trans-Canada Telephone System facilities from 9 a.m. to 10 p.m. Previous results are not directly comparable. As the first 6 months include the severe winter months, the results for them are much worse than for the balance of the year.

Future Development

The transcontinental open-wire lead has been developed to its maximum capacity. It is of interest to note that the *J* carrier capacity of the line has been reached only 8 years after the first broad-band carrier system was placed in service. The high rates of traffic growth now being experienced and the need for television facilities requires a new basic structure.

Long-term relief is being provided by a coast-to-coast radio-relay system carrying television and *L* carrier facilities. This system is now under construction with over-all completion scheduled for late 1957 or early 1958. A light-route microwave system installed earlier between Halifax and St. John for telephone service has been operating satisfactorily. It will be noted that the coaxial stage of development used in the United States has been avoided in Canada. Because of the timing, Canada has gone directly from open-wire to radio-relay operation.

The additional telephone circuits required for direct distance dialing (customer toll dialing with automatic machine switching) will be furnished economically over the new radio-relay structure. This system will also tie in with the new transatlantic cable.

Design of Electronic Equipment for Radio-Interference Reduction

A. L. ALBIN
ASSOCIATE MEMBER AIEE

H. M. SACHS
NONMEMBER AIEE

Synopsis: During a survey recently conducted for the U. S. Army, Navy, and Air Force, it was found that the control of radio interference was a serious problem to both designers of electronic equipment and to the military operational activities. Some of the critical areas of design that have affected equipment and system performance in the field are discussed herein. Several types of electronic equipment for ground and air-borne applications are discussed including radar, communications, and navigation apparatus. The effectiveness of practical suppression techniques such as shielding and filtering is also considered. Requirements of the current interference specifications are reviewed and techniques discussed for making conducted and radiated measurements of continuous-wave and broad-band interference sources.

THE Armour Research Foundation recently completed a study and evaluation of the radio-interference program of the services. The purpose of the study was to make a comprehensive survey and formulate recommendations for a long-range program of research and development, and to recommend measures which could be put into effect immediately in such areas as maintenance and operation of equipments in the field.

The survey was made by investigations conducted at military operational activities, industrial organizations, and government research laboratories. Interviews with engineers and operating personnel at these facilities indicated that, while many of the problems were operational in nature, others were caused by a lack of consideration of radio interference in the initial design of electric and electronic equipment. Much technical information is now available on procedures for interference-free design, and the services have made great strides in their efforts to awaken an interference consciousness in engineers not normally concerned with these problems. It was found, however, that organizations not ordinarily concerned with the radio-engineering aspects of interference, such as manufacturers of ships, electric motors, and vehicles, desired more information of a tutorial nature to acquaint them with applicable design, development, and measuring techniques. It is to this group that this paper is directed.

This paper will present some of the general design problems that are encountered, remedial measures that have proved effective in practice, and a brief discussion of applicable measurement techniques. In addition, the references will be found to provide valuable design information for specific applications.

General Suppression Techniques

NEED FOR EARLY CONSIDERATION

For effective application of radio-interference suppression, it is important to consider the problem early in the design stage. While considerable interference reduction can often be achieved by conservative design, it is frequently found that additional components must be incorporated in the equipment to obtain the desired degree of interference reduction. Consequently, it is of advantage to anticipate possible difficulties and to provide room in the equipment for such components. Furthermore, conventional parts may often be replaced by others with superior interference-reduction properties at little or no additional cost, provided the designer is aware of their application and availability.

SOURCES OF INTERFERENCE

Undesired coupling leading to radio interference may occur by radiation, induction, or conduction. Since so-called radiated measurements are often made in the induction field, it has become general practice to include the influence of both the near and far fields within the scope of radiated interference. Although not

strictly a rigorous interpretation, it serves as a practical distinction from the mode of transmission wherein coupling occurs by means of currents propagated along circuit conductors or ground paths. Fig. 1 illustrates representative interference sources, while Fig. 2 shows the aforementioned methods of interference propagation.

While interference generators may produce wave shapes of many varieties, those of interest herein may be grouped broadly into two general areas: broad-band and continuous-wave sources; see Fig. 3. Broad-band interference may be produced by pulses of short rise and decay times and narrow widths, which have energy content extending over a wide range of frequencies. A radar modulator, for example, produces a pulsed output signal at a fundamental repetition rate of 400 to 3,000 cycles per second (cps), yet may contain significant energy components as high as 30 megacycles. Continuous-wave interference is that produced at discrete frequencies because of such effects as harmonics, parasitic oscillations, and other generators of primarily sinusoidal waveform.

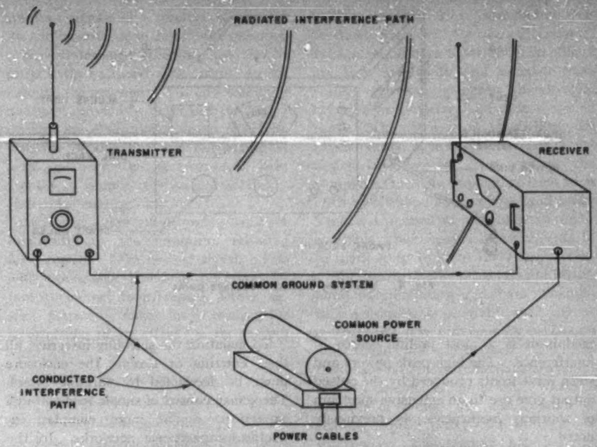

Fig. 2. Conducted and radiated interference propagation

Almost any radio transmitter can be a source of interference unless extreme care is given to control the generation of spurious emission. The need for accurate frequency control in very-high-frequency and ultrahigh-frequency communications has resulted in the use of crystal control at relatively low frequencies followed by frequency multipliers and power amplifiers to obtain the desired output characteristic. Each intermediate stage can radiate on its fundamental as well as on the harmonics of the output frequency. In addition, circuit resonances at frequencies removed from the operating point may result in generation of parasitic oscillations. Improperly designed or tuned transmitters may produce spurious side bands when modulated.

A microwave radar transmitter is seldom a problem to communications since its frequency is sufficiently removed to preclude interference to receivers other than those operating in the same band, and filters can readily be applied where overloading causes spurious responses in the receivers. On the other hand, the

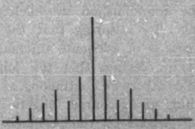
(CONTINUOUS WAVE)



(D) CW TRANSMITTER OUTPUT

Fig. 3. Typical interference wave shapes

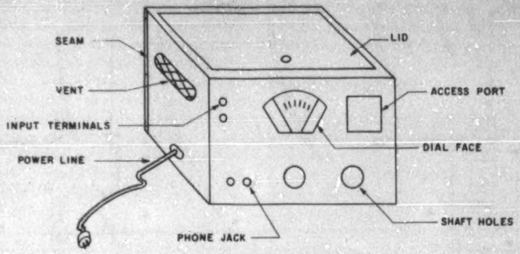


Fig. 4. Shielding enclosure leakage paths

modulator is a most prolific source of interference. The high peak powers and steep wave fronts produced by the pulsed output give rise to an extensive spectrum of spurious frequencies, as previously noted.

Not often suspected but a frequent offender is the superheterodyne receiver. Local-oscillator radiation from the antenna or chassis may be sufficient to block adjacent receivers on certain frequencies.

There are a number of other sources of interference, such as ignition systems, rotating machinery, and contacting devices, but a discussion of these factors cannot adequately be treated within the scope of this paper.

INTERFERENCE REDUCTION

Several preventive measures are available to the designer interested in obtaining equipment which is free of interference. In many cases interference-free components are available for assembly in complete equipments. Careful choice in component selection can do much to reduce the over-all suppression engineering. When installing systems where both transmitters and receivers are used, care should be taken to avoid locating high-level interference sources, such as radar modulators or radio-frequency transmitters, in proximity to the receivers.

When the afore-mentioned measures are insufficient, there are other means of controlling the interference. The primary methods by which such suppression may be accomplished are shielding and filtering. By ensuring that the equipment case is of adequate thickness, and by making certain that the joints are welded or otherwise continuous, as well as providing spring-contact fingers or conducting gaskets on the periphery of removable covers or doors, the induction and radiation fields can be contained within the equipment enclosure.

To maintain the shielding integrity, all lines entering or leaving the enclosure must be decoupled by suitable filters. These may consist of simple feed-through capacitors, or of more complex inductance-capacitance networks. In the presence of strong radiation at a fixed frequency, such as the microwave energy from a radar transmitter, tuned filters in the receiver antenna circuit are often quite effective. It is also necessary to make sure that all units are bonded to ground with a strap that offers low impedance to radio frequencies.

Equipment Design

It is well to consider some specific examples illustrating application of the foregoing techniques to equipment design.

RADAR MODULATORS

There are two principal sources of interference from a radar: the modulator and the radio-frequency transmitter. The radar modulator can produce considerable pulse energy at radio frequencies, which may cause severe interference to near-by communications equipment. In the design of the modulator there are three areas in which suppression must be accomplished:[1]

1. Enclosure design, to attenuate radiated interference.
2. Filter design, to reduce conducted interference.
3. Design of the high-voltage pulse cable and connectors.

An ideal enclosure should have no openings and should be of sufficient thickness to preclude case penetration by the interference energy. In practice, there must be openings to provide ventilation and permit accessibility for maintenance; see Fig. 4. In addition, there may be discontinuities in the shield for signal and power leads, control shafts, etc. To maintain the shielding effectiveness requires careful attention to all these possible sources of leakage.[2]

The following measures will help to maintain the desired shielding effectiveness:

1. Since seams which are riveted or bolted are ineffective for shielding at radio frequencies, they should be welded, brazed, or soldered such that the joint is continuous.
2. Removable panels or covers should have the finish removed from all mating surfaces. Spring-contact fingers or conductive gaskets will help provide good electrical contact around the periphery of the panel.
3. All openings for ventilation or drainage over 1/16 inch diameter should be screened with fine copper mesh. As an alternative, the opening may be designed with a sleeve which acts as a wave-guide attenuator when properly dimensioned.
4. Conductors which must carry pulse wave forms should be separated from low-level or d-c cables to prevent mutual coupling. The pulse leads should be well shielded and terminated in low-impedance connectors which are separate from all other leads. (One technique that has been adopted for an air-borne equipment was to mount the magnetron directly on the pulse-transformer housing, thus eliminating the need for a pulse cable between the modulator and transmitter.)

To prevent interference from being conducted out of the case on connecting leads, all leads entering or leaving the enclosure should be well filtered. Often the use of feed-through capacitors will give sufficient interference reduction; in severe instances, however, it will be necessary to use low-pass filters to decouple the noise voltages. To preclude coupling between input and output leads, they should be shielded and isolated so that interference will not be reintroduced on conductors leaving the equipment. It is also good practice to use well-grounded electrostatic shields between the high-voltage and low-voltage windings of power or filament transformers.

RADAR TRANSMITTERS

Because of the high peak power levels, a microwave radar transmitter can cause considerable interference to communications receivers, even if they are not tuned to the interfering frequency. This is caused by the Fourier components of the modulation frequency, which may produce side bands extending over hundreds of megacycles. Such interference may be coupled directly from the antenna or through case radiation. Case radiation may be considerably reduced by applying the shielding techniques previously described. The most effective measures for

Vol. 7
Pt. 1
1956

reducing antenna-radiated interference are to utilize wave forms containing only the minimum high-frequency harmonics actually required for the desired equipment performance and the reduction of receiver susceptibility. The latter problem will be considered in a later section.

COMMUNICATIONS TRANSMITTERS

While communications transmitters are not often susceptible to interference, they may produce considerable harmonic and spurious radiation. This is often caused by the need for getting the maximum power output from a given equipment within a limited space, which necessitates conserving the number of frequency-multiplying stages and, sometimes, overdriving the final amplifier.

An unstable oscillator is very susceptible to parasitic oscillations. Where practical, crystal control should be used and the oscillator should be loosely coupled to the following stage. Since capacitive coupling networks often permit the passage of harmonics and spurious radiations to succeeding amplifiers, a tuned coupling network is to be preferred. The power amplifier should not be used as a frequency multiplier, since it will contain a large undesired component at the fundamental frequency. The output stage should be designed for low distortion at the required power output to minimize the need for excessive grid excitation and heavy loading, both of which lead to the generation and transfer of spurious signals into the antenna.

If the foregoing measures have been followed, together with careful shielding and decoupling of the individual stages, the harmonic and spurious content of the radio-frequency carrier can be reduced to a low level. For further interference reduction, it may be necessary to insert a low-pass filter in the output circuit to reduce harmonic radiation The application of such design techniques will permit reducing undesired interference signals to as much as 80 decibels less than the carrier amplitude.

When installing the transmitter, care should be taken to avoid routing antennas and transmission lines near susceptible receivers. The use of shielded transmission lines will help considerably to reduce coupling from the antenna system.

RECEIVERS

While considerable interference reduction can be achieved at the source of the interference, much can be done to reduce receiver susceptibility. In some cases even properly designed and operated transmitters can produce interference or spurious signals in a receiver because of its nonlinearity or undesirable responses.

A well-designed receiver case should prevent the entrance of any signal except through the antenna. The case-shielding methods previously described for transmitters are also applicable to receivers. The use of shielding and decoupling of leads entering the receiver will help greatly to reduce receiver susceptibility caused by case penetration.

It is also important to reduce receiver bandwidth to the minimum required for reception of the desired signal. This will measurably assist in rejecting adjacent channel interference. Other design features which may reduce the interference or its effect on the output are:

1. High image-rejection ratio.
2. Balanced antenna input circuit.
3. Use of peak noise limiter.
4. Shielded antenna lead-in.
5. Tunable or fix-tuned antenna wave trap.
6. Receiver blanking for the duration of the interfering pulse.

The local oscillator of superheterodyne receivers may often be a source of interference to other receivers. Such interference can be reduced by operating the oscillator at minimum power level, by using internal shielding of the converter and oscillator stages, by employing electrostatically shielded coupling transformers, and by incorporating a radio-frequency amplifier stage.[3] The measures which can be applied successfully will, of course, depend on the operating characteristics of the system in which it is employed, e.g., radar, communications, navigation, etc.

Measurements

INSTRUMENTS

To permit evaluation of the degree of interference produced by an equipment and the effectiveness of interference-reduction measures, it has been necessary to develop standardized instruments and measuring techniques. For obtaining relative measurements it is common practice to use audio output meters which respond to the average or rms value of the receiver output. For engineering purposes, however, it has been found desirable to use an interference measuring set which responds to the peak value and provides information on the amplitude and spectral distribution of the interference. Such intruments, commonly called noise meters, usually consist of an antenna, amplifier, detector, indicator, and means for calibration.

The amplifier is a superheterodyne receiver preceded by an attenuator. Design requirements for such amplifiers are high sensitivity and signal-to-noise ratio, stability, constant bandwidth, accurate attenuators, and wide dynamic range. The choice of bandwidth depends on the type of interference signal under measurement; in general, the equipment must be capable of measuring both broad-band and narrow-band interference. Commercial instruments are now available which enable measurements to be made from 15 kc to 1,000 megacycles.

For measuring the peak value of broad-band interference, a slide-back vacuum-tube voltmeter is generally used. Some instruments have provision for both aural and visual null slide back. For continuous-wave measurements an average reading meter is provided. While a number of meters are also capable of reading "quasi peak," the difficulty of interpreting the reading has led the military services to adopt peak as the standard.

A calibrator is used to provide a standard voltage source with which the interfering signal may be compared. The unit of measurement is microvolts per unit bandwidth, which makes an allowance for receiver bandwidth variations. Much broad-band interference is of the impulse type and has been found to produce a response in the receiver proportional to the bandwidth. For such measurements an impulse noise generator has been developed which provides useful output as high as 1,000 megacycles. Some instruments utilize random noise calibration. The noise source is usually a shot diode or a gas tube. Calibration for continuous-wave measurements is made with a sine-wave generator operating at the input frequency of the amplifier.

Both vertical rod and horizontal dipole antennas are used when making tests of radiated noise, depending on the frequency of measurement. For locating point sources of interference, such as leakage in a cabinet, loop antennas are quite useful; however, difficulty in correlating their output with that of rod antennas precludes their use in field-intensity measurements.

For conducted interference the instrument is used as a 2-terminal radio-frequency voltmeter. A line-stabilizing network is provided to standardize the impedance of the line across which the interference voltage is measured.

Figs. 5 and 6 illustrate the placement and connection of the noise meter when used to make conducted and radiated interference measurements respectively.

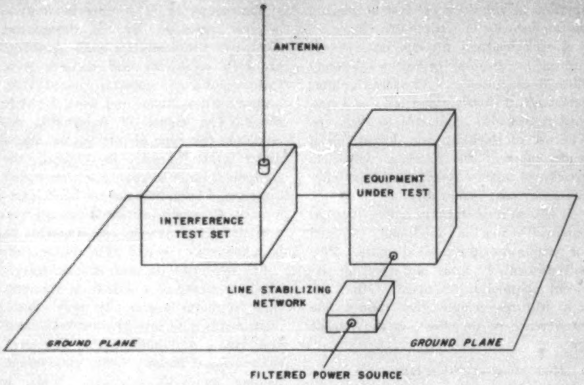

Fig. 5. Test arrangement for conducted interference measurements

TEST AREAS

For making interference measurements where the ambient interference level may be quite high, as in industrial areas, a suitable screen room must be used. Such rooms are available in a number of sizes and several types of construction, depending on the degree of attenuation required. The walls may be constructed of copper mesh, solid copper or iron, or a composite of these materials. The simplest structure consists of a single-wall shielding enclosure; where higher ambient levels are encountered, a double-shield construction is employed. This is most commonly of the cell type with panels of the enclosure shielded individually and the cells then joined together. Another method of construction utilizes two walls completely insulated from each other except at one common ground point. To maintain the shielding effectiveness of the screen room, the electric power must be brought through a line filter which will reject interference on the power line.

In many cases, reflections from a screen room may prove quite troublesome in obtaining useful readings. In addition, some equipments may be too large to measure in a screen room of reasonable size. In such instances, it is necessary to choose a suitable site in an open area where the ambient interference level is relatively low over the frequency range of interest. Some work is currently being conducted toward correlating screen room measurements with those made in open areas.[4]

Specifications

To insure uniformity in limits and methods of measurement for electronic equipment procured by the military services, a number of radio-interference specifications have been issued, covering specialized applications of electronic equipment.

Specification *MIL-S-11748 (Sig C)*[5] is employed by the U. S. Army for testing electronic equipment. Radiated measurements are required from 0.15 to 1,000 megacycles at test distances based on the minimum expected distance from susceptible communication equipment. Conducted measurements are made over the range of 0.15 to 40 megacycles.

MIL-I-6181B[6] is employed by the U. S. Air Force and Navy Bureau of Aeronautics for interference tests on electric and electronic equipment. A number of objective tests are required to evaluate the extent of generation or susceptibility of an equipment to interference. Radiated measurements are required from 0.15 to 150 megacycles for equipment capable of producing broad-band interference. The Air Forces have found that suppression over this range will generally provide satisfactory interference reduction up to 1,000 megacycles.

On the other equipments, including those emitting continuous-wave and pulsed-continuous-wave radiation, measurements are required from 0.15 to 1,000 megacycles. The antenna is located 1 foot from the equipment. Conducted interference measurements are made from 0.15 to 20 megacycles. Measurements are not required on leads interconnecting the various units of a given system.

On some equipments, tests are also required for susceptibility to conducted audio interference and to conducted and radiated radio-frequency interference. Finally, measurements are made of spurious front-end receiver responses and spurious antenna radiation from transmitters and receivers.

For ship-borne or ground-based electronic equipment, *MIL-I-16910A (Ships)*[7] is utilized by the Navy Bureau of Ships. This specification covers radiated measurements over the frequency range of 14 kc to 1,000 megacycles, and conducted interference from 0.15 to 100 megacycles. The antenna is located 3 feet from the equipment under test for measuring radiated interference. Specifications are provided for receiver oscillator radiation and spurious transmitter radiation.

Conclusions

It has been attempted to present the major interference problems confronting the designer of electronic equipment, and remedial measures have been suggested. In brief, the latter include:

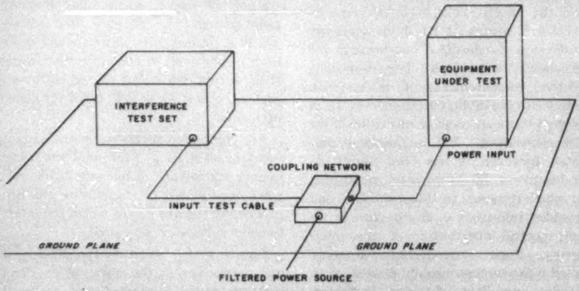

Fig. 6. Test arrangement for radiated interference measurements

1. Case shielding.
2. Filtering of input and output leads.
3. Good radio-frequency bonds.
4. Conservative design.

The importance of considering interference reduction in the initial design cannot be stressed too strongly. Although interference suppression generally goes hand in hand with good design practices, it must also be considered in its own light at a very early stage to be most effective.

Method of Measuring Spot Size of Cathode-Ray Tube

R. B. KUHN
NONMEMBER AIEE

D. LEVINE
NONMEMBER AIEE

THE determination of the spot size of a cathode-ray tube has been, at best, a subjective process. Thus, the shrinking-raster method of measuring spot size relies on the judgment of the observer to determine when a set of lines appears to merge. Similarly, any attempt to measure the spot diameter with a microscope is also dependent upon the observer because of the way the flux density varies over the area of the spot.[1]

This paper describes an objective method for determining spot size. The spot size is defined as being equal to the side of a square within which the current density in the Gaussian distribution about a stationary electron beam $I_c\epsilon^{-k^2r^2}$ may be redistributed uniformly with current density I_c.[2] Given this definition, the constant k is expressed as

$$k=\frac{\sqrt{\pi}}{w}=\frac{1.7725}{w} \qquad (1)$$

Nomenclature

$H(x)\equiv\frac{2}{\sqrt{\pi}}\int_0^x \epsilon^{-u^2}du$ = probability integral
I_c = current density at center of electron beam
$I_c\epsilon^{-k^2r^2}$ = current density anywhere in electron beam
k = constant determined by definition of spot size for Gaussian spot; it is equal to $\sqrt{\pi}/w$ herein
L_0 = reference level of light flux, measured when flying spot is focused on center of widest or reference slit on test mask
L_M = light flux incident upon photocathode when flying spot is focused on center of slit other than the reference slit
L = light flux incident on photocathode after passing through slit
$r^2=x^2+y^2$
W = width of largest slit and each opaque dividing strip
w = width of the cathode-ray-tube spot
x = distance from center of spot to leading edge of slit
y = direction of long dimension of a slit
λ = width of any slit
ρ = light flux density at center of spot
$\rho\epsilon^{-k^2r^2}$ = light flux density anywhere in the spot

Instrumentation

The method requires an instrument, Fig. 1, consisting chiefly of a mask, an objective lens to focus the cathode-ray-tube spot onto the mask, and a condensing lens to focus the light passing through the mask onto a phototube. The object of the condensing lens is the exit pupil of the objective lens. A filter is placed in the light beam to pass only the short persistent component of the phosphor light radiation. In practice, the filter would undoubtedly be mounted on the object lens; however, its position is unimportant. The instrument may be designed so that the measured value of the spot size has a rms uncertainty of less than 4 per cent.

The mask consists of an opaque background broken by slits of various dimensions; see Fig. 2. The opaque area between any two slits, as well as the largest slit, each has a width W at least four times the width of the largest spot to be measured. The width of the narrowest slit is approximately four-fifths the size of the smallest spot to be measured. The length of each slit is 20 times the width of the largest spot to be measured. At the time that this paper was prepared, a prototype instrument similar to the one shown in Fig. 1 had been built, but no actual measurements had been made.

Theory

When the spot is focused within a single slit of width λ, the relative light output, neglecting phosphor decay, is given by

$$\frac{L}{L_0}=\frac{1}{2}\{H[k(x+\lambda)]-H(kx)\} \qquad (2)$$

See the Appendix for derivation of equation 2.

Equation 2 has its maximum value when

$$x=-\frac{\lambda}{2} \qquad (3)$$

i.e., when the spot is centered in the slit. If the maximum is denoted by subscript M, then

$$\frac{L_M}{L_0}=\frac{1}{2}\left[H\left(\frac{k\lambda}{2}\right)-H\left(-\frac{k\lambda}{2}\right)\right]=H\left(\frac{k\lambda}{2}\right) \qquad (4)$$

Substitution of the definition of k into equation 4 yields

$$\frac{L_M}{L_0}=H\left(\frac{\sqrt{\pi}}{2}\,\frac{\lambda}{w}\right) \qquad (5)$$

The light passing through a slit is measured by placing the output of the phototube on a suitable recorder. The light through a mask, Fig. 3(A), as

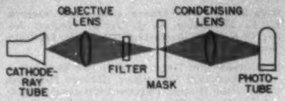

Fig. 1. Representation of spot-size measuring instrument

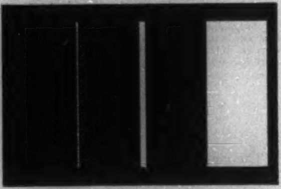

Fig. 2. Mask for spot-size measurement. Length of each slit is 3.588 inches; widths, from left to right, are 0.007, 0.021, and 0.063 inch. Dimensions are for mask used with prototype instrument

recorded at the phototube output is illustrated in Fig. 3(B) for the case where the spot size is equal to the width of the second slit. When the spot is in the center of the first slit, there is no significant limiting of the light output, and the value of L_0 is determined; see Fig. 3(C), left. However, when the spot is at the center of a slit that is equal to the spot size, 21 per cent of the light is obstructed by the opaque area; see Fig. 3(C), center. In Fig. 3(C), right, the light contours permit the further reduction of maximum light associated with a slit of half the spot size to be visualized.

After L_M/L_0 is determined, equation 5 may be used to solve for spot size. Alternatively, the graph of Fig. 4 may be employed. The curve drawn here has a point of inflection at

$$\frac{w}{\lambda}=\frac{\sqrt{\pi}}{2}=0.88623 \tag{6}$$

as derived elsewhere.[3] Consequently, in the region of this spot-size value, a small error in the determination of the light ratio has a minimum effect on the accuracy of the spot-size measurement.

Error Analysis

The maximum relative error is given by

$$\frac{\Delta w}{w}=\left(\frac{w}{\lambda}\right)\epsilon^{\frac{\pi}{4}\left(\frac{w}{\lambda}\right)^{-2}}\left(\frac{\Delta L_M}{L_0}-\frac{L_M}{L_0}\,\frac{\Delta L_0}{L_0}\right)+\frac{\Delta\lambda}{\lambda} \tag{7}$$

as shown elsewhere.[3]

For a 1-per-cent error in slit width and in each recorded reading, the maximum relative error and rms error are expressed as

$$\frac{|\Delta w|}{w}(\max)\leqq 0.02\,\frac{w}{\lambda}\,\epsilon^{\frac{\pi}{4}\left(\frac{w}{\lambda}\right)^{-2}}+0.01 \tag{8}$$

and

$$\frac{\Delta w}{w}(\mathrm{rms})\leqq\left[0.0002\left(\frac{w}{\lambda}\right)^2\epsilon^{\frac{\pi}{2}\left(\frac{w}{\lambda}\right)^{-2}}+0.0001\right]^{1/2} \tag{9}$$

as derived elsewhere.[3]

The error functions are plotted in Figs. 5 and 6 for either 1- or 2-per-cent maximum error in each reading. From the graphs it follows that the minimum relative error in the measured spot size is obtained when the ratio of the spot size to the slit width is 1.25; for a 1-per-cent recording and reading error, the rms relative error is less than 4 per cent over the range

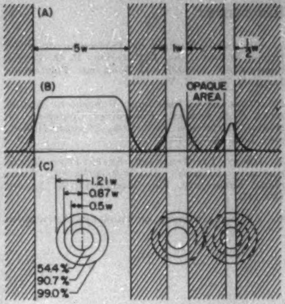

Fig. 3. Test chart function

A—Test mask
B—Light variation for swept beam
C—Light distribution about centered spot

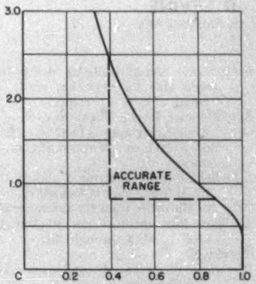

Fig. 4. Spot-to-slit ratio w/λ as function of light ratio L_M/L_0

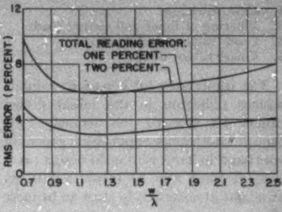

Fig. 5. Rms value of relative spot-size error as function of spot-to-slit ratio w/λ

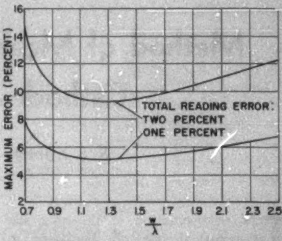

Fig. 6. Maximum value of relative spot-size error as function of spot-to-slit ratio w/λ

$$0.8<\frac{w}{\lambda}<2.4 \tag{10}$$

The maximum error is 6.5 per cent over this range, which corresponds to the accurate range region specified in Fig. 4. Consequently, a mask designed for measurement of a wide range of spot sizes may have adjacent slit widths in a 3-to-1 ratio.

It also follows from Figs. 5 and 6 that, for a 2-per-cent recording and reading error, the rms relative error is less than 8 per cent over approximately the same range as equation 10, while the maximum relative error is 12 per cent.

Since the term $\Delta\lambda/\lambda$ in equation 7 is constant, the errors between relative readings with the same instrument are dependent mainly on the recording apparatus. Thus, when one instrument is used for all determinations, relative spot sizes can be measured more accurately.

The basic relation of this report is equation 2, which was derived on the assumption that the distribution of the electrons in a beam is Gaussian, and that the light output of the phosphor (neglecting decay) is directly proportional to the current density. Consequently, the error equations will apply only when these assumptions are closely approximated.

Conclusions

If the light flux density of the cathode-ray tube has a Gaussian distribution, the spot size, as defined in the foregoing, can be determined in an objective manner. The accuracy of the determination is dependent on the ratio of the spot size to the slit width, errors in the recording apparatus, and errors in the slit-width measurement.

Appendix. Derivation of Relative Light Output

When the cathode-ray-tube spot is focused on a slit of width λ, the light passing through the slit is expressed as

$$L=\rho\int_{x}^{x+\lambda}\epsilon^{-k^2x^2}dx\int_{y}^{y+5W}\epsilon^{-k^2y^2}dy \qquad (11)$$

The integrals of equation 11 are converted to normal probability integrals by the substitutions

$$y=\frac{w}{k}$$

and

$$x=\frac{v}{k}$$

The result is

$$L=\frac{\pi}{4k^2}\{H[k(x+\lambda)]-H(kx)\}\times \{H[k(y+5W)]-H(ky)\} \qquad (12)$$

Since $5W$ is 20 times the width of the largest spot to be measured, the second factor of equation 12 is at least as large as

$$[H(ky+20\sqrt{\pi})-H(ky)]$$

For all practical purposes, the latter term is equal to 2 when the spot is nearly centered in the y direction. Thus equation 12 becomes

$$L=\frac{\pi}{2k^2}\{H[k(x+\lambda)]-H(ky)\} \qquad (13)$$

When λ is four times the width of the largest spot to be measured, the amount of light passing through the largest slit is given by

$$L_0=\frac{\pi}{2k^2}[H(kx+4\sqrt{\pi})-H(kx)] \qquad (14)$$

With the spot centered in the x direction, the quantity in brackets is, for all practical purposes, equal to 2. Thus, equation 14 becomes

$$L_0=\frac{\pi}{k^2} \qquad (15)$$

All the slits are $5W$ long. Therefore, the light passing through any single slit is given by equation 15, and the ratio of L to L_0 is expressed as

$$\frac{L}{L_0}=\frac{1}{2}\{H[k(x+\lambda)]-H(kx)\} \qquad (16)$$

Discussion

G. R. Spencer (Philco Corporation, Lansdale, Pa.): The method described in this paper provides an answer which is meaningful only to the extent that the light flux density distribution approximates the Gaussian law, but the authors do not reveal here any means for determining how nearly their distributions approach Gaussian curves. Indeed there are several factors which tend to cause departures from the true Gaussian distribution, the most important of which are electron lens aberrations, space charge conditions, aperture masking, and phosphor saturation. Further, misalignment of gun parts and stray magnetic fields frequently cause marked lack of circular symmetry.

It seems appropriate, therefore, to point out that an instrument which provides a picture of the brightness distribution across a line traced by the electron spot would be of far greater value in most applications. Such an instrument has been described adequately in the literature,[1] and some equipments using this principle have been used at Philco, and perhaps elsewhere, for several years. Fig. 7 illustrates a typical output signal in which the brightness distribution across two adjacent lines of one field of a television raster is represented. The known line spacing provides a convenient calibration datum.

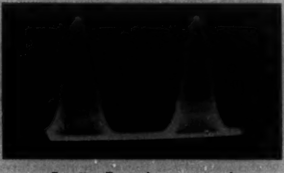

Fig. 7. Typical output signal

It is conceivable that the answers obtained with the apparatus described by the authors, in spite of the uncertainties as to their precise meaning, may be useful in some applications. Will the authors suggest applications for which their method would give meaningful results? And for what ranges of beam currents and anode voltages has this technique been found practicable?

R. B. Kuhn and D. Levine: We appreciate Mr. Spencer's comments and his calling attention to Mr. Green's apparatus.[1] The introduction to our paper would have been written differently had this reference been known to us earlier.

In view of the well-known variety of spot shapes that are to be found under certain conditions,[2] it was decided to concentrate on properly defined spots in the design of our equipment. It should be realized that this viewpoint taken represents that of a "using" organization as contrasted with one that is concerned with tube development. Consequently, if a spot is seriously deformed because of poor electron optics, it would result in rejection of the tube (on the part of the user) without the necessity of taking measurements.

While the analysis of our instrument is limited to a Gaussian variation of light flux, alternative derivations can be provided for any other known distribution. In effect, though, one must start with information concerning the flux distribution, and the assumption made appeared the most reasonable following a literature survey.[3] Consequently, our equipment admittedly finds no application to studies of the influence of various factors on the shape of the spot. For this purpose the instrument developed by the Philco Laboratories appears to be ideal.

Basically, both developments have as their aim the providing of an objective measure of spot size to replace the subjective shrinking-raster method or other visual means. To achieve this goal, both approaches use aperture techniques. Mr. Green has designed his apparatus about an aperture that is very narrow relative to the spot size, while our equipment employs an aperture having a width of the same order of magnitude as the spot size; see equation 10.

The first-mentioned approach has the advantage of providing detailed information about spot shape, while the latter technique requires very uncritical sweep positioning. This factor is of importance to our immediate application, which is to check cathode-ray tubes installed in radar plan-position indicators.

Two New Total Radiation Pyrometers

W. DERGANC
ASSOCIATE MEMBER AIEE

S. N. HOWELL
NONMEMBER AIEE

Synopsis: The measurement and control of temperature are basic to all industrial processes. Modern automatic machinery exploits the economy achieved by a continuous flow of product. Such machinery requires instrumentation capable of measuring the temperature of moving material in process for maximum efficiency. Total radiation pyrometers are useful for this purpose, and there is a continuing demand from industry for more sensitive, accurate, and versatile instruments. This paper describes two new pyrometers* applicable to a wide variety of industrial and laboratory measurements. They combine good spectral response, high sensitivity, and rapid response, with stability and accuracy adequate for most requirements. These factors are discussed in relation to the design of the pyrometers. The basis for transferring a radiation measurement to a temperature by calibration and some of the limitations involved are also considered.

Brief Description of Instruments

TYPE IR-2 SYSTEM

THE first instrument to be described is the Servotherm† type *IR-2* radiation pyrometer system, shown in Fig. 1, and consisting of a pyrometer head, an amplifier, and power supply. This is a general-purpose unit for measurements in the range from 60 to 1,300 C (degrees centigrade) and is capable of maintaining calibration under the ambient conditions encountered in manufacturing plants. The output is directly applicable to proportional automatic control systems. Fig. 2 is a simplified section of the pyrometer head, and Fig. 3 shows a partial schematic of the amplifier and power supply circuits. The system functions as follows.

Incoming radiant energy is collected by the Servofrax (arsenic trisulfide glass) lens and, after interruption by the mechanical chopper at a 15 cps (cycles per second) rate, is focused on a Servotherm thermistor bolometer detector. This energy is compared with similarly interrupted energy from an internal reference radiation source via a second detector, bridge-connected with the first. The bolometer bridge is biased with direct voltages balanced to ground, and the cyclic interruption of the energy produces cyclic variations of the bolometer resistances. Any difference in energy levels between incoming and reference radiations produces an alternating voltage output from the bridge to the preamplifier grid. The phase of this output voltage depends on which radiation level is higher, since the radiation from either chopper itself is equal to the ambient level of the pyrometer head.

After amplification by the preamplifier and main amplifier units, the output is rectified by a synchronous rectifier on the chopper shaft. This produces a direct voltage polarity sensitive to the energy levels; i.e., a source hotter than the reference produces a positive voltage output, and a colder one, a negative.

The internal reference source is always used to null the incoming radiation, making it possible to utilize full amplification for high-differential sensitivity at all times. Once the pyrometer is set for a given temperature, small deviations from it appear as relatively large voltage outputs which may be used for manual indication and control or as the input signal to an automatic system.

The field of view of this system is one degree square and the lens focuses from 1.5 feet to infinity. The system time constant, once set at a given temperature, is approximately 250 milliseconds. The time required for the reference source to stabilize at a new setting varies from about 30 seconds to five minutes depending upon the initial and final conditions.

TYPE IR-1 SYSTEM

The type *IR-1* system is a fast and very sensitive general-purpose laboratory instrument for measurements from ambient to 1,000 C. It employs essentially the same electronic system as the *IR-2* but a different pyrometer head; see Figs. 4 and 5. In this system incoming energy is collected by a first-surfaced spherical mirror. The energy is interrupted by a motor-driven chopper at 180 cps and focused on a thermistor bolometer detector. This detector is bridge-connected with a compensating thermistor in the same housing and its output is amplified and rectified as for the *IR-2* system. The output is proportional to the difference in radiant energy between the chopper radiating at ambient temperature and the incoming radiation. Focusing is accomplished by moving the detector-preamplifier assembly, and a scale covering from two feet to infinity is provided. The system covers a 1-degree square field, and the over-all response time is 25 milliseconds. A feature of this unit is the parallax-free periscope sight which permits accurate aim in detecting hot spots, etc. The sight contains a built-in output meter so that simultaneous viewing of target and output signal is possible. Illumination balance is achieved by a controlled meter light and adjustable polaroid filter disks for the target.

Design Considerations

SPECTRAL RESPONSE

Available Energy

Fig. 6 shows the relative energy versus wave length for blackbodies at temperatures between 20 and 920 C. Note that 75% (per cent) of the total energy, represented by the area under the curves, is on the long wave-length side of the radiation maximum, and that most of the total energy is at wave lengths greater than one micron. For example, at 1,000 C, less than 0.5% of the total energy is below that wave length. At lower temperatures, considerably less total energy is available, and the distribution shifts to longer wave lengths. To utilize most of the available energy, a pyrometer should detect the energy from 1 to 12 microns or more. In some cases, such as the determination of total emissivity, a response to 25 microns is required for accurate results.

The spectral sensitivity of the pyrometers is limited by three factors: the collecting optics, detector window, and detector response. The last-mentioned is relatively flat in the 1- to 25-micron region so that the first two items are the essential limitations in this case.

IR-2 Optics

For the *IR-2* system, arsenic trisulfide glass was selected for the lens. As

Pt. 1
1956

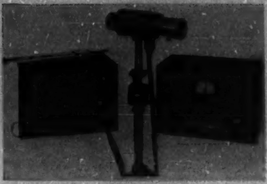

Fig. 1. Type IR-2 pyrometer system showing power supply (left), pyrometer pickup head (center), and amplifier unit (right)

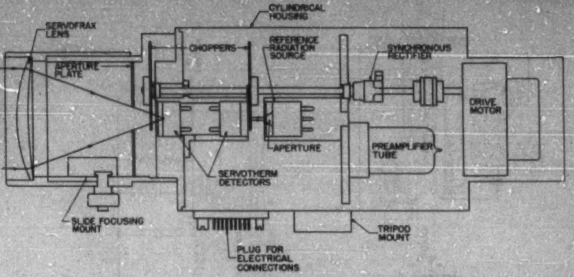

Fig. 2. Simplified sectional view of type IR-2 pyrometer head

shown in Fig. 7, this glass has good transmission in the 1- to 12-micron region. It is the first available material with far infrared transmission that can be fabricated in any reasonable size, that does not require special mounting or handling, and that is impervious to most chemicals. It has other desirable properties of a true glass, such as ease of cleansing.

The lens is a meniscus type, two inches in diameter, and *f 1.25*. The design was adjusted to keep the on-axis aberrations under the desired 1-degree field of view. Larger fields, up to about five degrees may readily be achieved by increasing the detector dimensions. Smaller fields may be accomplished by using a slower lens with reduced aberrations; this, however, reduces the over-all system sensitivity which, for given parameters, is inversely proportional to the *f* number of the lens. The detector window will modify the over-all response of this system. When arsenic trisulfide is used, the effect is to lower the over-all transmission while maintaining the same general shape of the curve. It should be pointed out that the arsenic trisulfide curve is for uncoated material. Coating can materially improve the transmission in the passband, but it is relatively expensive and has not been found necessary.

IR-1 Optics

This system utilizes an *f 0.8* first-surfaced collecting mirror of 3.5 inches focal length. The surface material is rhodium which has relatively flat and high transmission out to 25 microns so that the spectral response is limited by the detector window alone. Two typical response curves for such windows (other than arsenic trisulfide) are shown in Fig. 7. That for the coated silver chloride includes from four to 16 microns.

The relation of relative energy to temperature in pyrometer and blackbody systems is shown in Fig. 8.

DETECTORS

The detectors used in both pyrometers are of the flake thermistor type. They are housed in hermetically sealed capsules and they combine time constants of two milliseconds, excellent sensitivity, and uniform spectral response with ruggedness and long-term stability. The voltage output for square-wave interruption of energy is

$$V/\Delta W=K\left[1-\exp\frac{-t}{T}\right] \qquad (1)$$

where

V = voltage output for
ΔW = incremental radiation
T = detector time constant
t = time
K = A constant

For a typical detector as used in the *IR-2* system of 1 by 1 by 0.01 millimeter thick, the sensitivity is 250 volts per watt of incident radiation. The 15 cps interruption rate used in this system permits utilization of practically all of the available sensitivity, while in the *IR-1*, the response was compromised somewhat in favor of increased speed of response. When properly biased, the bolometer bridge may be operated within six decibels of theoretical noise which is the thermal noise of the thermistors. The rms noise output under typical conditions is about two microvolts at an impedance level of one megohm. A detector used in the *IR-2* system is shown in Fig. 9.

ELECTRONIC SYSTEM

Full exploitation of the available signal-to-noise ratio from the detectors requires extreme care in the design and construction of the electronic system. The detector bias must be noise free at the microvolt level, and insulation resistance in excess of 50,000 megohms to ground must exist at the input circuit to avoid extraneous noise currents. Amplification in the low-frequency region without introducing noise from a variety of sources calls for extremely well-filtered grid and plate voltages, minimum grid current, d-c filament supply, nonmicrophonic construction and components, and careful attention to grounding and shielding. The last-mentioned is particularly important in view of the proximity of the drive motors to the input circuit.

The preamplifiers built into the pyrometer heads meet these requirements. Low-noise, nonmicrophonic tubes and components are employed, and the operating conditions carefully adjusted for the best signal-to-noise ratio. Sufficient amplification is available to allow the use of a flexible shielded cable to the main amplifier unit.

The design of the main amplifier, Fig. 3, is conventional. Calibrated step attenuators are used to permit positive reset to a calibration point. The 3-stage feedback amplifier with a gain of about 7,500, drives a phase splitter whose output is fed to the synchronous rectifier. The d-c output from the latter is *RC*-filtered and fed to a differential output stage. This combination was found superior to the use of a selective amplifier tuned to the chop frequency. It includes energy components in the detector output, equation 1, over the fundamental, and eliminates the stability problem of synchronizing motor speed to amplifier tuning. Since a negative supply is used for the cathode returns, the output is both balanced and balanced to ground. Unbalanced output may be taken from terminal *A* to ground. The output stage will deliver about four milliamperes into 1,000 ohms and is designed to saturate on overloads to protect the recorder. Two special power supplies were designed to meet the re-

quirements of well-filtered bolometer bias and preamplifier voltages. The bolometer bias supply uses a radio-frequency oscillator operating at about 70 kc. The oscillator output is fed to a carefully balanced rectifier-filter circuit. Since the plate supply to the oscillator is well regulated, output disturbances are minimized. Small residual variations appear balanced across the output. Since the bolometer bridge is balanced, these tend to cancel out. Filament power for this supply is also derived from a regulated source. These precautions plus careful attention to reducing 60-cycle pickup and microphonics make it possible to operate the biased bolometer bridge within six decibels of theoretical resistance noise for normal main supply variations from 105 to 125 volts.

The regulated filament supply uses a power audio-oscillator operating at 7 kc. Plate power for this unit is also well regulated. Part of the a-c output is used to power the bolometer bias oscillator and rectifier. The remainder is rectified and filtered and supplies d-c filament and grid bias voltages for the preamplifier.

Reference Radiation Source

The reference source, Fig. 9, as used in the *IR-2* system, utilizes a small nichrome-wound heater element and an arsenic trisulfide window. The radiation temperature of the heater is sensed by a small bead thermistor which is bridge-connected with the control potentiometer. The bridge is excited at line frequency and its output after amplification is fed to a thyratron which controls the power input to the source. The amplifier phase shift is arranged to produce proportional output control at the balance point. Extremely stable control of the source is obtained in this manner.

Two alternative sources have been employed. The first is similar to that just described but it utilizes a platinum-wire winding instead of the bead thermistor as the temperature sensing element. This eliminates the limitation on operating temperature imposed by the thermistor rating. The second is a combination heater and liquid-cooled unit which allows operation down to and below ambient temperature.

Calibration and Application

General

The use of total radiation pyrometers to measure temperature is, in theory, subject to many errors, in fact, to all of

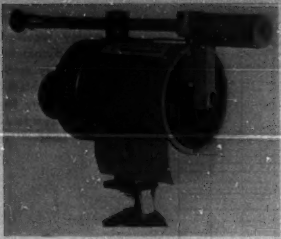

Fig. 4. Type IR-1 pyrometer head

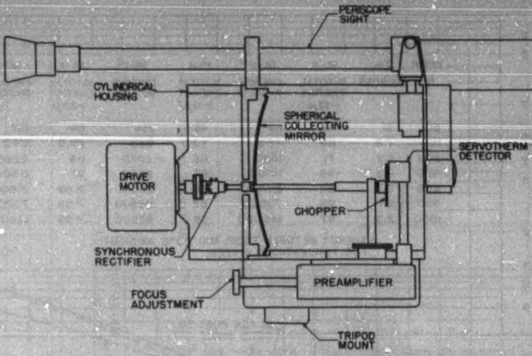

Fig. 5. Simplified sectional view of type IR-1 pyrometer head

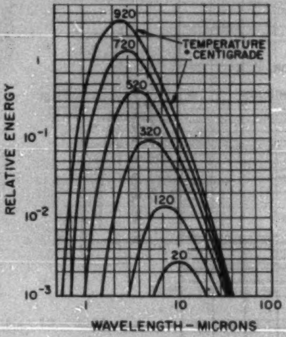

Fig. 6. Energy distribution of blackbody radiant energy with respect to wave length at different temperatures

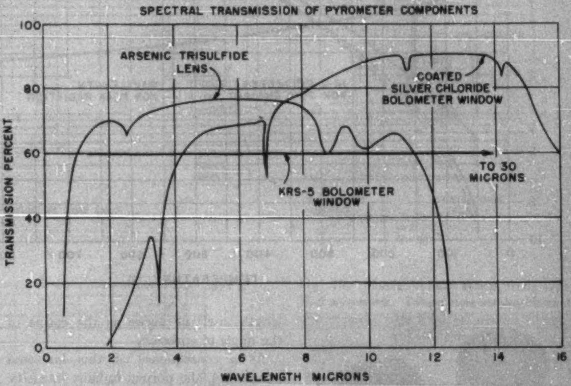

Fig. 7. Spectral transmission of pyrometer components

those found in measuring radiant energy, which suggests a formidable list of factors affecting the accuracy of such devices. In practice this is not the case. Simple calibration of the instrument under controlled conditions is usually adequate to produce accuracies comparable to other temperature-measuring devices used in the plant. A typical example is the manufacture of sheet film. This process required careful control of the temperature of film moving at high speeds. Thermocouples or thermistors cannot accurately show the film temperature. However, a stationary piece of film may be set up under controlled temperature conditions, and the pyrometer calibrated against this piece. This calibration may then be transferred to the film in process.

Such a transfer calibration is usually preferable to attempting a relationship to a standard blackbody calibration. The latter, however, is useful when emissivity factors are to be determined, and under other special conditions. A working knowledge of blackbody radiation is also required for the intelligent use of any total-radiation pyrometer, and a brief review of blackbody radiation laws follows.

BLACKBODY RADIATION

There are three bases for relating total radiation to temperature: the Planck equation defining the spectral distribution of energy, the Wien displacement law, and the Stefan-Boltzmann law of total radiation. These are expressed mathematically as follows.

$$\text{(Planck)}\quad W\lambda = C_1 \times \lambda^{-5}\left[\exp\frac{C_2}{\lambda T} - 1\right]^{-1} \tag{2}$$

$$\text{(Wien)}\quad \lambda_m T = 2{,}900 \tag{3}$$

$$\text{(Stefan-Boltzmann)}\quad W = KT^4 \qquad W_1 = K(T^4 - T_0^4) \tag{4}$$

where

$W\lambda$ = radiant energy emitted per unit-area per unit-increment of wave length
$\left.\begin{matrix}W\\W_1\end{matrix}\right\}$ = radiant energy emitted per unit area
C_1 = first radiation constant
C_2 = second radiation constant
T = absolute temperature of radiating body, degrees Kelvin
T_0 = absolute temperature of surroundings, degrees Kelvin
λ = wave length in microns
λ_m = wave length in microns for maximum radiant energy
exp = 2.718, Napieran base
K = Stefan-Boltzmann constant

A family of curves of equation 2 was plotted in Fig. 6. Equation 3 gives the relationship of wave length to the temperature at which W_λ is maximum. It is convenient for rapidly estimating the

energy distribution and is determined by setting the derivative of equation 2 equal to zero, and solving. Integration of equation 2 from zero to infinity with respect to λ gives the total radiated energy; see equation 4.

A further important property of blackbodies is the Lambert cosine law: The radiation from a blackbody for all wave length intervals varies as the cosine of the angle of emission.

As a consequence of this law and equation 4, the normal radiant intensity produced by a source of area A at a distance d is

$$P=5.67\times10^{-8}\,\frac{A}{\pi d^2}\,(T^4-T_0^4)\ \text{watts per square meter} \quad (5)$$

For a fixed field of view, the ratio of A to d is fixed, and for a 1-degree pyrometer field, equation 5 becomes

$$P=5.54\times10^{-12}\,(T^4-T_0^4)\ \text{watts per square meter} \quad (6)$$

Emissivity

The application of total radiation pyrometers to temperature measurement is based on equation 4 Since most radiating surfaces do not obey this law exactly, an emissivity correction factor is assigned

$$W_2=Ke(T^4-T_0^4) \quad (7)$$

This assumes that the radiation from T_0 is black, a condition which is approached in these pyrometers. Equation 7 gives the total energy radiated by a "gray" body; i.e., one which exhibits all of the blackbody properties except that its energy curve is displaced downward.

The emissivity is a function of temperature and, to define properly the spectral radiation, its variation with wave length must also be considered. Further, since ordinary bodies do not necessarily obey the cosine law, there is a variation with viewing angle. In radiation pyrometry, it is customary to use a single factor e_t, the total emissivity. This is an acceptable procedure if the assumptions involved are borne in mind.

Emissivities may be determined by a pyrometer such as the type *IR-1* with wide-band (1- to 25-micron) response. The instrument is calibrated against a known blackbody. Then, when aimed at the test material under a specified set of viewing conditions, the pyrometer will not indicate the true temperature T but some lower value T_1, termed the

radiation temperature. For a non-blackbody

$$W_2 = K(T_1^4 - T_0^4) \tag{8}$$

Combining equations 7 and 8 gives, where T_0 is small,

$$e_t = \left(\frac{T_1}{T}\right)^4 \tag{9}$$

The total emissivity varies widely for different materials. At 700 C the value of e_t is 5% for polished silver, 10% for polished platinum, and 85% for iron oxide. At room temperature, the emissivity of bright copper is several hundred per cent less than at elevated temperatures. For clean metals, e_t is approximately representable by an equation of the form

$$e_t = BT^b \tag{10}$$

where B and b are constants.

For porous, nonmetallic materials,

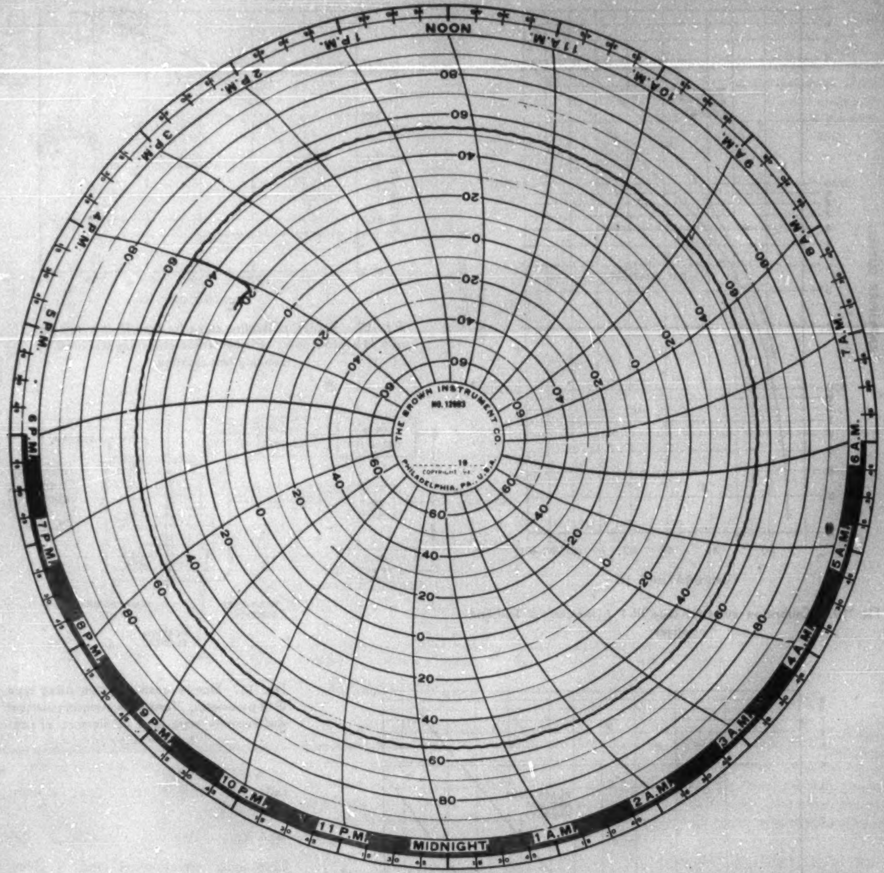

Fig. 14. Temperature chart for system of Fig. 13 for 1-day period of operation with control temperature at 54 C

e_t is high, regardless of the visible color of the material. Some nonmetallic materials have emissivities which decrease with increasing temperature. An additional consideration is the distinction between emissivity, which is the property of a material determined under standardized conditions, and emittance, which is the corresponding property of the surface. Thus, the published value of an emissivity may not be applied indiscriminately without consideration of surface condition and viewing angle, as well as temperature. For typical values of e_t see reference 1.

ACCURACY

Factors affecting the accuracy of calibration may be separated into those inherent in the instrument itself, and those applicable to the method of use. These will be considered in turn after discussion of one factor, ambient temperature, which can affect both. In so far as the instruments are concerned, there are a number of variables to be considered such as chopper blade temperature, variation of detector output, and variations in the electronic system. For practical purposes, as determined by measurements, the variation in the *IR-1* system may be compensated for by measuring the ambient temperature close to the head and computing output accordingly. For the *IR-2* system, repeated checks under ordinary plant variable conditions have shown no significant effect on output. This is accomplished by the automatic temperature regulation of the internal heat reference. This feature favors the *IR-2* for automatic process control.

The instruments contain a number of components which directly affect the output indication. The first is the collecting lens or mirror. These necessarily must be kept clean if the incoming radiation is to be held constant at the detectors. The latter are extremely stable chemically, with lattice structures, established by sintering at 1,300 C. After initial aging during manufacture, errors introduced by this source are negligible. Every reasonable effort has been made to stabilize the electric circuit and components so that frequent reset and calibration are unnecessary. An additional component in the *IR-2* system is the reference source. As indicated previously, its stability is dependent on a bead thermistor or platinum wire, inherently stable materials. The net result as indicated by preliminary laboratory tests is that calibration-checking once a week is all that is necessary for the most exacting measurements.

Factors external to the instrument itself are considerably more variable. The condition of the atmosphere is of major importance. Dirt, smoke, vapors, and humidity can all affect the output reading. The effect of ambient air conditions on the measured sample can be large. An object can have its surface temperature changed by five or more degrees by a slight breeze, with the pyrometer measuring surface temperature. Thus the ambient wind condition on the sample must be considered in measuring surface temperature. Allowances may be made for all of these effects provided the average proportions are kept constant and the distance from source to pyrometer is not varied. This allowance may be made either by a correction factor, or by calibrating and measuring under identical conditions, the latter being preferable wherever it is possible.

Humidity is of particular importance, since it is generally an uncontrollable factor. However, for distances under ten feet and ordinary plant conditions, the correction is very small and usually masked by other sources of error.[2]

The surface condition of the material to be measured is of utmost importance. Calibration should always be made on a representative sample, to avoid errors from this source. If the surface condition varies, several calibrations with different samples should be made to determine the extent of the possible error, and the corrections to be made. As a corollary to this factor, the angle of view should be considered, since the calibration will vary with this factor for most bodies.

A final precaution to be taken is the avoidance of stray radiation. This is a very important, often disregarded, source of error. Since an ordinary body is not a perfect absorber, it will reflect radiation from near-by objects. If a radiation source is in proximity to the source being measured, energy from it is likely to enter the pyrometer by reflection and to affect the indication. The filter-coated silver chloride detector window which cuts off radiation below three microns is helpful in eliminating stray radiation from visible sources such as lights, etc. An aperture plate limits the field of view on the type *IR-2* system. Additional radiation shielding should be used where there is any question of stray radiation affecting the readings.

One further consideration is of interest. In many continuous-flow processes, an absolute temperature reading is not needed. The essential requirement is to be able to reproduce a process reading over a period of time. For such conditions of operation, the type *IR-2* system will give entirely satisfactory service over long periods, without recourse to elaborate calibration schemes.

TYPICAL CALIBRATION

Type IR-1

Typical calibration curves for the type *IR-1* system are shown in Figs. 10 and 11. The low-temperature curve was taken by looking at the blackened side of a metallic container with a controlled temperature water bath. The high-temperature curve was taken by looking into the muffle of a small laboratory furnace. For comparison, the black-body energy for the temperatures concerned is also plotted. This is the difference between the total energy for a temperature and the energy of the chopper blade at ambient temperature for the 1-degree field. At ambient temperature, the amplifier output (except for residual noise) and the energy are zero. Except for a scale factor, the curves are quite close. Fig. 10 shows the threshold sensitivity to be about 1 by 10^{-7} watts per square centimeter.

Type IR-2

A calibration curve for the type *IR-2* system is shown in Fig. 12. This was taken on a blackened hot plate. The surface temperature was measured with a small thermocouple located at the center of the field of view. The calibration is for the full aperture of the collecting lens, and the standard reference source. Higher temperatures are read by stopping down the lens. With the reference set at 100 C, the average differential sensitivity is about ±5 C for full output. The incremental sensitivity is less than 0.25 C, and the over-all control accuracy of a typical installation is better than 0.5 C

APPLICATION

The type *IR-1* system is applicable to a wide variety of measurements such as the determination of chimney hot spots, line joint and transformer overheating, flame temperatures, emissivity measurements with regard to radiation losses, vacuum-tube plate dissipation where nonsinusoidal excitation makes computation difficult, and other determinations limited only by one's imagination. The efficacy of the type *IR-2* system to control applications is best illustrated by an example. Fig. 13 shows a simple control system in which the temperature of a water bath was sensed by the *IR-2* unit. The output of the unit was used to control input to the heater on an on/off basis, and a temperature-sensing element of the mercury type with recorder were used to measure the effectiveness of control. Fig. 14 is a typical temperature chart for the system of Fig. 13 and indicates the stability which is obtainable, even at the low control temperature of 54 C.

Transistor Power Amplifiers with Switched Mode of Operation

A. G. MILNES
MEMBER AIEE

A CONVENTIONAL circuit for class *B* power amplification with transistors is shown in Fig. 1(A). The two transistors (p-n-p) are connected in the common emitter arrangement and in the absence of signal are quiescent at a point on the output characteristics such as *P* in Fig. 1(B). When a sinusoidal voltage signal is applied as base drive, the transistors operate on a load line such as *PQ* in alternate half-cycles, and a sinusoidal output is obtained. At any intermediate point on the load line *PQ* the active transistor sustains a collector-emitter voltage equal to the difference between the battery voltage and the instantaneous output voltage. The product of this collector-emitter voltage and the current flowing gives the instantaneous power loss in the transistor (excluding the small dissipation associated with the base drive). Simple calculations based on these considerations show that the maximum possible efficiency of this arrangement is 78 per cent and that maximum power dissipation occurs in the transistor when operating with an output that is 64 per cent of the possible full output voltage.

Power dissipation in the transistor with resultant temperature rise is the factor that principally limits the output power that can be handled by a given unit. In recent papers, however, the advantages of operating the transistor as a switch that is either of very high or of very low impedance, depending on the controlling conditions, have been recognized.[1,2] In the high-impedance condition, corresponding to, say, point *P* in Fig. 1(B), the transistor sustains voltage but there is little current flow and therefore low dissipation in the junction, and in the low-impedance condition the current flow is large but the collector-emitter voltage is small, as for point *Q* in Fig. 1(B), and therefore the dissipation remains low. The transition between *P* and *Q* is made rapidly and so represents very little heat generation within the transistor. Thus with switching circuit arrangements there can be appreciable uprating of the power-handling capabilities of a given transistor; for example, the values quoted for a typical power transistor are 10 watts in class *B* and 40 watts in switching applications.

Switching transistor power supply converters depending on these circuit principles have been described recently,[3,4] but possible applications of the technique to power amplifiers seem not to be discussed in the literature. A number of amplifier circuit arrangements based on this principle are therefore presented and discussed.

Half-Wave Switching Circuit with D-C Signal

As a simple form of the type of circuit to be examined, consider a p-n-p transistor connected between a load resistance and an a-c supply, as in Fig. 2(A), with a rectifier diode in series that ensures half-wave action. The base drive of the transistor is provided by the direct-voltage signal in series with an alternating bias voltage of the same frequency as the supply and the resistor R_b serves merely to restrict the base current to a safe limit under all input conditions.

A p-n-p transistor assumes a high impedance (cut-off) condition when the potential of its base is positive with respect to both the emitter and collector potentials. Thus, for the bias and signal voltages in Fig. 2(B), the transistor is cut off between the angular position θ and π-θ and the full supply voltage appears across the emitter and collector terminals as shown in Fig. 2(C). However, in the intervals 0 to θ, and π-θ to π, the base potential tends to be negative with respect to the emitter, and the transistor becomes conducting. Almost the full supply voltage appears across the load resistance in these intervals, providing the base drive current is adequate to permit the required load current flow (for example, from Fig. 1(B) a base current flow of 30 milliampere peak is required for a peak load current of 450 milliampere). In the second half-cycle, π to 2π, the supply voltage is blocked by the diode rectifier in the circuit. For the idealized circuit behavior thus described the cut-off angle is given by

$$\sin\theta=\frac{V_{d-c}}{V_{\text{bias}}} \tag{1}$$

and the mean load voltage by

$$V_{\text{load}}=\frac{V_p}{\pi}(1-\cos\theta) \tag{2}$$

where V_{bias} is the peak value of the sinusoidal bias voltage and V_p is the peak value of the supply voltage.

From equations 1 and 2, the theoretical output characteristics, Fig. 2(K), curve 1, can be calculated. If the bias voltage is of reversed phase with respect to the supply voltage (the dots shown in Fig. 2(A) indicate the in-phase condition), and if the signal voltage is negative, the load voltage wave form becomes of the type shown in Fig. 2(C) since excess of bias over signal voltage then produces the base polarity corresponding to conduction and not cut-off. The output characteristic that results is shown as curve 2 in Fig. 2(K). From curves 1 and 2 it is clear that an intermediate condition such as 90-degree lead bias is of interest. The wave forms for this are given in Fig. 2(F) through (J). The circuit equations are as follows:

$$\cos\theta=\frac{V_{d-c}}{V_{\text{bias}}} \tag{3}$$

$$\text{and } V_{\text{load}}=\frac{V_p}{2\pi}(1+\cos\theta) \tag{4}$$

thus, the resulting characteristic is the straight line 3 in Fig. 2(K).

If the bias voltage is between one-fifth and one-tenth of the supply voltage, the required signal voltage is similarly small; and since the base current is an order of magnitude less than the load current the characteristics of the circuit correspond to some degree of power amplification. The magnitude required for the bias voltage is determined by the base current required to permit flow of the peak load current and by the sharpness of switching required by dissipation considerations.

A d-c supply source is a possible alternative to the half-wave a-c source shown in Fig. 2(A): the output characteristic for this condition (somewhat nonlinear) may be readily calculated if required.

Paper 56-94, recommended by the AIEE Solid State Devices Committee and approved by the AIEE Committee on Technical Operations for presentation at the AIEE Winter General Meeting, New York, N. Y., January 30–February 3, 1956. Manuscript submitted October 19, 1955; made available for printing February 24, 1956.

Half-Wave Switching Circuit with A-C Signal

Fig. 3 shows the behavior of the basic half-wave circuit controlled by an a-c signal of supply frequency.

For a bias voltage leading the supply by 90 degrees the idealized wave forms are as shown in Fig. 3(B) through (D). If the bias leads by ψ degrees the circuit equations are

$$V_{\text{bias}} \sin(\theta+\psi) = V_{\text{sig}} \sin\theta \qquad (5)$$

and $$V_{\text{load}} = \frac{V_p}{2\pi}(1+\cos\theta) \qquad (6)$$

Theoretical output characteristics obtained from these equations are given in Fig. 3(E) and it will be seen that for this a-c signal condition with a 90-degree lead bias there is loss of sensitivity at high and low output levels. Curve 3 for the in-phase bias condition does not represent true switching operation of the transistor since cut-off and conduction periods of the kind discussed previously do not occur. Therefore, if on curve 3 an output intermediate between full and zero is required, the transistor while conducting also sustains voltage, and so appreciable heat loss occurs which must be dissipated by the unit.

For the characteristics of Fig. 3(E) the signal voltage is either in phase with or in reverse phase to the supply. Characteristics for any other phase-angle relationship between signal and supply are easily derived.

Full-Wave Parallel Circuit with A-C Output

A full-wave output is obtained if two transistors active on alternate half-cycles are connected in parallel as shown in Fig. 4(A). For the signal voltage in phase with the supply and the bias leading by 90 degrees, the idealized wave form of load voltage is that in Fig. 4(C). (The arrows indicate that both triggering angles advance with increase of signal.)

The theoretical output of the parallel circuit is, of course, twice that for the half-wave arrangement and the characteristic (for a 90-degree lead bias) is similar to curve 1; see Fig. 3(E). An experimental characteristic for this condition is given as curve 1 in Fig. 4(D). The signal voltage plotted is the input to the signal voltage transformer which had two secondary windings, each of half the number of primary turns. The bias windings formed part of a similar transformer and the input was 10 volts, rms. Hence the switching and signal voltages actually operating in the transistor base circuits were of about 5 volts in magnitude. The resistors R_b limiting the base current flow were of 50 ohms. The supply voltage (60 cycles per second) was 50 volts rms and was perhaps somewhat too high for transistors with a 60-volt peak collector rating, although it gave satisfactory wave forms at room temperature.

A—Circuit arrangement
B through D—Ideal wave forms for 90-degree lead of bias voltage
E—Theoretical output characteristics

For the signal range of zero to 10 volts the input current to the signal transformer varied between 15 and 30 milliamperes; thus the input power was of the order of 1/4 watt. The change in power output of curve 1 between these signal limits (neglecting form factor considerations) is approximately 10 watts. Thus the power gain of the circuit arrangement may be estimated in this way to be about 40 (or 16 decibels). This is a rough-and-ready value given to indicate the order of gain, and nothing more.

With the circuit operating in the switched mode resulting in curve 1 of Fig. 4(D), the temperature rise of each transistor was quite small (a few degrees centigrade). With no bias applied for switching purposes, curve 2 was obtained. This is of much higher sensitivity than curve 1, but the temperature rise in each transistor was then substantial (say, 40 degrees centigrade or more). Thus the switched mode of operation in amplifiers greatly reduces the dissipation and therefore the temperature rise, but there is considerable loss in sensitivity. Switched operation has a second advantage in that the output curve is not so directly related to the immediate transistor parameters (which are temperature-dependent) and therefore is virtually a stabilized (or negative-feedback) characteristics.

In these particular tests the 90-degree lead of the bias voltage was obtained from an electromechanical phase-shifting regulator, but in practice the required phase advance is more conveniently obtained with a capacitor circuit.
